The Climate Hazards Group InfraRed Precipitation with Stations development process was carried out through U.S. Geological Survey (USGS) cooperative agreement #G09AC000001 "Monitoring and Forecasting Climate, Water and Land Use for Food Production in the Developing World" with funding from: U.S. Agency for International Development Office of Food for Peace, award #AID-FFP-P-10-00002 for "Famine Early Warning Systems Network Support," the National Aeronautics and Space Administration Applied Sciences Program, Decisions award #NN10AN26I for "A Land Data Assimilation System for Famine Early Warning," SERVIR award #NNH12AU22I for "A Long Time-Series Indicator of Agricultural Drought for the Greater Horn of Africa," The National Oceanic and Atmospheric Administration award NA11OAR4310151 for "A Global Standardized Precipitation Index supporting the US Drought Portal and the Famine Early Warning System Network," and the USGS Land Change Science Program.

A Quasi-Global Precipitation Time Series for Drought Monitoring

By Chris Funk^{1,2}, Pete Peterson², Martin Landsfeld², Diego Pedreros^{1,2}, James Verdin¹, James Rowland¹, Bo Romero², Gregory Husak², Joel Michaelsen², and Andrew Verdin³

Abstract

Estimating precipitation variations in space and time is an important aspect of drought early warning and environmental monitoring. An evolving drier-than-normal season must be placed in historical context so that the severity of rainfall deficits may quickly be evaluated. To this end, scientists at the U.S. Geological Survey Earth Resources Observation and Science Center, working closely with collaborators at the University of California, Santa Barbara Climate Hazards Group, have developed a quasi-global (50°S–50°N, 180°E–180°W), 0.05° resolution, 1981 to near-present gridded precipitation time series: the Climate Hazards Group InfraRed Precipitation with Stations (CHIRPS) data archive.

Background

Since 1999, U.S. Geological Survey (USGS) and University of California, Santa Barbara (UCSB) scientists, supported by funding from the U.S. Agency for International Development (USAID), the National Aeronautics and Space Administration (NASA), and the National Oceanic and Atmospheric Administration (NOAA), have been developing techniques for producing precipitation grids in data sparse regions. Focusing primarily on Africa, this work supported drought monitoring efforts by the USAID Famine Early Warning Systems Network (FEWS NET). Early research focused on combining models of terrain-induced precipitation enhancement (Funk and Michaelsen, 2004) with interpolated station data (Funk and others, 2003). These data served a number of early warning objectives. The data supported the creation of standardized precipitation index maps (Husak and others, 2007), making it easier to identify areas experiencing hydrologic extremes; allowed for the improved interpretation of African climate forecasts (Husak and others, 2011); and informed the first USGS/UCSB African drought analyses (Funk and others, 2005; Verdin and others, 2005).

More recently, USGS and UCSB combined new resources of satellite observations, average precipitation from stations, and rainfall predictors such as elevation, latitude, and longitude to build high resolution [0.05 degree, approximately 5 kilometers (km)] global gridded monthly precipitation averages to create the Climate Hazards Precipitation Climatology (CHPClim) (Funk and others, 2012). These improved monthly means for the period 1980–2009 were then used to remove systematic bias from monthly satellite-based precipitation fields using the ratio of the CHPClim to the satellite-only monthly mean. This bias removal method has been adopted as an effective approach to representing terrain-related precipitation effects (Funk and others, 2007). Further processing to blend station observations with these unbiased satellite rainfall estimates was used to produce the 1981 to present Climate Hazards Group InfraRed Precipitation with Stations (CHIRPS) dataset, to support FEWS NET drought monitoring activities (Funk and Verdin, 2010).

Data Inputs to the CHIRPS

The main data sources used in the creation of CHIRPS were: (1) the monthly precipitation climatology, CHPClim, temporally disaggregated at each grid cell location into 72 pentadal (6-pentads per month) long-term average accumulation values, in millimeters—these 72 mean values describe the expected annual sequence of rainfall at each location; (2) quasi-global geostationary thermal infrared (IR) satellite observations from two NOAA sources, the Climate Prediction Center (CPC) IR (0.5 hour temporal resolution, 4 km spatial resolution, for 2000–present) and the National Climatic Data Center (NCDC) B1 IR (3 hour temporal resolution, 8 km spatial resolution, for 1981–2008) (Janowiak and others, 2001; Knapp and others, 2011); (3) the Tropical Rainfall Measuring Mission (TRMM) 3B42 product from NASA, (Huffman and others, 2007; Huffman and others, 2011); (4) atmospheric model rainfall fields from the NOAA Climate Forecast System, version 2 (CFSv2) (Saha and others, 2010; Environmental Modeling Center, 2011); and (5) in situ precipitation observations obtained from a variety of sources including national and regional meteorological services. All the data sources

were compiled as 5-day rainfall accumulations. The pentad (5-day total) is the focus of the CHIRPS estimation process because sub-monthly time steps are needed for monitoring and modeling agricultural drought (Verdin and Klaver, 2002).

The CHIRPS Procedure

CHIRPS is the product of a two part process. First, IR Precipitation (IRP) pentad rainfall estimates are created from satellite data by calculating the percentage of time during the pentad that the IR observations indicate cold cloud tops ($<235^{\circ}$ K), and converting that value into millimeters of precipitation by means of previously determined local regression with TRMM 3B42 precipitation pentads. The IRP pentads are then expressed as percent of normal by dividing the values by their long-term (1981–2012) IRP means. These unitless values represent variations in time from the long-term mean (below normal, normal, or above normal rainfall). The percent of normal IRP pentad is then multiplied by the corresponding CHPClim pentad to produce an unbiased gridded estimate, with units of millimeters per pentad, called the Climate Hazards Group IR Precipitation (CHIRP). In the second part of the process, stations are blended with the CHIRP data to produce the final product, CHIRPS.

The IRP estimate represents the temporal component of the rainfall accumulated during a pentad, while the CHPClim represents the spatial component. This approach has been determined to effectively represent some of the systematic climate effects of complex terrain (Funk and others, 2007).

In some cases, there are missing IRP values due to incomplete satellite coverage. These data gaps, which primarily occurred during the 1980s, were filled in using CFSv2 data. The CFSv2 estimates were bias corrected in the same way as the IRP estimates, by using the ratio of CHPClim pentad to the long-term pentadal mean of the CFSv2.

The CHG Station Climatology Database

The Climate Hazards Group (CHG) at UCSB has developed an extensive archive of in situ daily, pentadal, and monthly precipitation totals. These observations come from a variety of sources such as: the monthly Global Historical Climate Network (GHCN) version 2 archive (Peterson and Vose, 1997), the daily GHCN archive (Durre and others, 2010), the Global Summary Of the Day dataset (GSOD) provided by NOAA's National Climatic Data Center, the World Meteorological Organization's Global Telecommunication System (GTS) daily archive provided by NOAA CPC, and over a dozen national and regional meteorological services.

There are a number of challenges trying to integrate station data from so many sources. The first issue is duplication of reports from different sources. Another concern is incomplete observations through time that could bias the long-term

mean at locations where data are disproportionately missing for a given decade. These issues were addressed by creating time-series over a list of anchor locations. Sources were considered sequentially, in order of their expected quality. Starting with the national datasets (which, though temporally and spatially disjointed, are expected to be of high quality), all locations were added to a anchor list. After all the national datasets were included, stations were added from regional and global sources, one at a time. For each new source, stations were only added to the anchor list if they were outside of a 10-km radius from any station already in the list. Stations within the 10-km radius are assumed to be duplicates and are used to fill missing values in the anchor stations. Once the anchor list and corresponding list of duplicate stations was complete, a precipitation time-series was built at each anchor location based on the ranking of the sources. Currently there are 52,743 anchor locations used in the production of CHIRPS.

Comparisons between the different station data sources and high quality daily observations from the originating national meteorological agencies indicated that the GTS and GSOD have substantial numbers of “false zeros”, that is, data values that have been incorrectly reported as zeros. A screening procedure was developed to flag and remove these potential false zeros.

If a GTS or GSOD station recorded a zero value on a day when the daily CHIRP value was above the expected daily rainfall intensity, that daily rainfall station value is treated as missing. Additional checks are made for spurious zero values for the pentadal and monthly accumulations. If the station reported zero for pentad or monthly values in the GTS or GSOD, but CHIRP indicated 7 mm or more for pentadal or 20 mm or more for monthly, the station data is treated as missing. Lastly, if a lower ranking source reports a non-zero value while the higher ranking source reports zero, the non-zero value is selected.

The automated station processing used in the CHIRPS produces a 1981 to near-present dataset suitable for drought monitoring and trend analysis. Because this archive is quality controlled by an automated procedure, it is not as closely curated as the monthly station data that go into longer latency global precipitation products like those produced by Global Precipitation Climate Center (Schneider and others, 2013) or the Global Precipitation Climatology Project (Adler and others, 2003; Huffman and others, 2009).

Blending Stations to Produce the CHIRPS

For each grid location in the CHIRP domain, the five nearest station observations are used to calculate an adjustment ratio for the CHIRP value. Each station is assigned a weight proportional to the square of their expected correlation. Closer stations receive higher weights. These five weights are then scaled to sum to 1 and used to blend the station data into

a single modifier (ratio) that can be used to adjust the CHIRP estimates. This ratio was capped at 3.0 to limit the possible impact of bad station data.

The CHIRP modification process also accounts for the estimated correlation of the CHIRP (0.5). The square of this value (0.25) and the square of the estimated correlation of the closest station are used to determine the relative “mix” between the interpolated station-adjusted CHIRP and the unmodified CHIRP. At a station location, where the expected correlation is 1, the relative mix would be as 1^2 is to 0.5^2 (80 percent adjusted and 20 percent raw CHIRP). Where the expected correlation of the nearest station is 0, the CHIRPS becomes identical to the CHIRP. The CHIRPS blending procedure is an inexact process, one that is not constrained to re-create the station values exactly. Even at a station location, the weighting procedure will still include values from four neighbors if the CHIRP fields indicate a positive correlation. The estimate will also include a contribution from the CHIRP. These algorithm decisions were based on a desire to mitigate the effect of potentially inaccurate observations, and especially false zeros, which can arise from the misreporting of missing data.

The CHIRP-station blending process is carried out at the pentadal and monthly time scales since there are a greater number of stations reporting at the monthly level. Pentadal CHIRPS values are adjusted such that their sum equals the total monthly CHIRPS.

For Africa, daily CHIRPS values are also created. Using daily cold cloud duration percentages (%CCD), daily rain/no-rain events are determined. The corresponding pentadal rainfall is partitioned among the daily rain events proportional to their %CCD.

CHIRPS Availability

Two CHIRPS products are produced operationally: a rapid preliminary version, and a later final version. The preliminary CHIRPS product is available, for the entire domain, soon after the end of a pentad. The preliminary CHIRPS uses only GTS stations, which are available within a 1 day delay. Other station datasets, GHCN, GSOD, take up to approximately 15 days to completely report data for all stations. These data are used to produce the final CHIRPS products, which are available sometime after the 15th of the following month. Final monthly, rescaled pentads and daily products are calculated at that time.
