TECHNICAL MEMORANDUM

USEPA Ace Services Site Pump Test Results

BVSPC Project 46118.126 BVSPC File D.3 4 November 13, 2000

# **INTRODUCTION**

In August 2000, a pump test was conducted at the Ace Services site in Colby, Kansas. The purpose of the pump test was to characterize the High Plains aquifer in the vicinity of the Ace Services site. Results of the pumping test will be used to model the hydraulic properties of the aquifer and to develop a design for a pump and treat remedial alternative for the Ace Services site. Three 72-hour pumping tests were conducted at three separate hydrologic zones within the aquifer to determine the transmissivity and hydraulic conductivity of the aquifer.

The City of Colby, Kansas relies upon the High Plains aquifer for its source of potable water (Figure 1). The High Plains aquifer is the principal source of water for the High Plains region. The High Plains aquifer consists primarily of sediments within the Ogallala Formation of Miocene age. The Ogallala consists of unconsolidated gravel, sand, silt, and clay. Locally, it also includes caliche, which is deposited as thin, discontinuous, layers within the upper portions of the formation. The Ogallala Formation was deposited by an extensive eastward flowing system of braided streams that drained the eastern slopes of the Rocky Mountains during the late Tertiary Period.

Unconsolidated deposits of Quaternary age overlie the Ogallala Formation. These deposits consist of gravel, sand, silt, and clay, much of which is reworked material that was derived from the Ogallala Formation. Deposits of loess overlie the Ogallala Formation or the unconsolidated Quaternary sediments at some locations.

FIGURE 1

Averaged 1997-1999 Saturated Thickness for the High Plains Aquifer in Kansas

Modified from U.S.G.S., 1997

## **SITE GEOLOGIC CONDITIONS:**

The lithology of the unconsolidated sediments, determined from soil samples collected during the drilling of the extraction and observation wells, indicates a highly stratified aquifer consisting of sand, gravelly sand, silt, and clay. The thickness of the unconsolidated sediments (Ogallala Formation) was approximately 230 feet thick. Multicolored shale of the Pierre Shale Formation underlies the unconsolidated sediments at 230 feet. The site subsurface stratigraphy is generalized by the following:

| Depth (ft) | Lithology                              | Remarks                   |
|------------|----------------------------------------|---------------------------|
| 0 - 30     | Silt, Sandy Silt (Loess)               | Dry                       |
| 30 - 57    | Sand and Silty Clay                    | Dry                       |
| 57 - 105   | Silt, Clay, and Sand                   | Dry to moist              |
| 105 - 135  | Sand, some gravel w/ Silty Clay layers | Shallow Aquifer Zone      |
| 135 - 145  | Sand and Clay (w/ interbedded caliche) | Shallow Aquifer Zone      |
| 145 - 190  | Gravelly Sand w/ thin clay lenses      | Intermediate Aquifer Zone |
| 190 - 207  | Clay and Silty Clay                    | Semi-Confining Unit       |
| 207 - 230  | Gravelly Sand w/ thin clay lenses      | Deep Aquifer Zone         |
| 230 +      | 230 +                                  | Bedrock (Pierre Shale)    |

#### **REGIONAL HYDROGEOLOGY**

The average saturated thickness of the High Plains aquifer in Kansas is approximately 90 feet. Water in the High Plains aquifer generally is under unconfined conditions. However, in some locations, water levels in wells completed in portions of the aquifer may rise or fall slightly in relation to the regional water table because of artesian pressure created by local confining beds. Generally the ground water gradient within the aquifer is from west to east. Water moves in response to the slope of the water table, which typically averages between 10 to 15 feet per mile. On the basis of these average gradients and aquifer hydraulic properties, the regional velocity of water that moves through the aquifer is estimated to average about 1 foot per day. Regional transmissivity values typically range from 40,000 to 60,000 gallons per day/ft with storage coefficients ranging from 0.14 to 0.27 (Miller and Appel, U.S.G.S. Ground Water Atlas, 1997).

## SITE HYDROGEOLOGY

Water levels measured during the remedial investigation indicate a slightly downward gradient within the aquifer surrounding the Ace Services site. Locally ground water flows to the east-southeast at horizontal gradients ranging from 0.0022 - 0.0032 ft/ft. Continuous water level monitoring prior to the pump test activities indicated that the shallow and intermediate zones within the aquifer function as a typical unconfined aquifer. However, monitoring data from the deep zone, collected prior to the pumping activities suggest that this lower zone acts as a semi-confined unit. Diurnal fluctuations in hydraulic head prior to the pump test occurred only in observation wells screened in the deep zone. These fluctuations suggest significant lateral influence by water supply wells pumping from the deep zone portion of the aquifer.

## **PUMPING TESTS**

Pumping tests were conducted at the Ace Services site within the Ogallala aquifer in Colby, Kansas from July 31 to August 10, 2000. Three 72-hour pump tests were conducted within each hydrologic interval. Changes in water levels within the three extraction wells and nine observation wells were measured during pumping tests using pressure transducers attached to a Hermit 3000 data recording device. An atmospheric transducer was also installed near the surface in one of the wells (MW-6) to monitor atmospheric pressure changes during the test. The data recorders were programmed to take readings at 1-minute intervals during the duration of the tests.

The extraction wells were screened at three different intervals: shallow, intermediate, and deep zones within the aquifer. The observation wells consisted of three well nests of three wells per nest. Each nest of wells contained a well screened in the shallow, intermediate, and deep zones of the aquifer. A plan of the extraction wells and observation wells is shown in Figure 2. The following table gives well numbers, locations, elevation of top of casing, depth to static water level, and the screened interval.

#### Table 1

A 1.5-horsepower submersible pump was used to conduct the shallow zone pump test while a 20-horse power pump was used to conduct the pump tests in the intermediate and deep zones. A flow meter was installed at the well head to monitor the discharge rate. The discharge water was piped approximately 50 feet to a sanitary sewer manhole for disposal, as per permission by the City of Colby public works department.

# **TEST ACTIVITIES**

The deep zone pump test was conducted from August 1 to August 4, 2000 at a pumping rate of 105 gallons per minute (gpm). The test lasted for 68 hours and drawdown data from the deep zone monitoring wells initially indicated that this zone behaved like a semi-confined aquifer (larger drawdowns over time). However, some drawdown was measured in the shallow extraction well EX-2-S (0.25 ft) and the intermediate extraction well EX-21, (1.1 ft) immediately adjacent to the deep zone extraction well indicating significant vertical leakage from the overlying intervals.

The intermediate zone pump test was conducted from August 4 to August 7, 2000 at a pumping rate of 187 gpm. The test was conducted for 69 hours and up to 6.6 feet of drawdown was measured in the observation wells within the intermediate zone. Lesser amounts of drawdown were measured in EX-2S (2.2 ft) and EX-2D (2.4 ft), immediately adjacent to the intermediate pumping well. Negligible drawdowns were measured in the shallow observation wells and were not used in the pump test analysis because of the difficulty of filtering out the background aquifer fluctuations and atmospheric effects.

The shallow zone pump test was conducted from August 7 to August 10, 2000 at a rate of 30 gpm for 63 hours. Due to the limited zone of saturation within the upper portion of the aquifer, little to no drawdown was measurable in the observation and non-pumping extraction wells.

## **TEST LIMITATIONS**

The tests were limited by several factors; the pumping rate for each test could not exceed 150-200 gpm, the pumping tests were limited to a maximum of 72 hours, and the wells were constructed in the three distinct zones (partial penetration) because of analytical/treatment considerations. Also, difficulties occurred at the beginning of each test with relation to establishing a constant pumping rate that would yield sufficient drawdowns in the adjacent observation wells. As a result, the intermediate and deep zones may not have been stressed sufficiently and/or may not have been pumped long enough to generate a cone of depression that would yield precise estimates of transmissivity and specific yield. To compensate for uncertainties in early time data, the late time data was used to perform curve matching. Overall, late time data is considered more accurate in unconfined aquifers for estimating transmissivities and storage coefficients.

#### ANALYSES

Several methods of analysis were used to determine solutions that most closely matched the conditions within the aquifer at the Ace Services site. The aquifer is generally considered to be under unconfined flow conditions. As a result, the Neuman (1975) method is thought to best analyze pumping test data within unconfined aquifers. The Neuman method was implemented during analysis of the intermediate pump test data. The Neuman method assumes that:

- The aquifer is unconfined and has an "apparent infinite extent"
- The aquifer is homogeneous, isotropic, and of uniform thickness
- The well is pumped at a constant rate
- Well diameter is small, so well storage is negligible
- Flow is unsteady to the pumping well
- The well penetrates the entire aquifer

Several factors involved with the pump tests at the Ace Services site could cause significant variations with relation to evaluation of the data by the Neuman method. The biggest factor is that the pumping wells did not fully penetrate the aquifer. There are also large portions of the aquifer that are not homogeneous and isotropic.

The Moench method, derived from Neuman's solution, may be better suited to the testing conditions that occurred at the Ace Services site. The Moench method is an analysis used when partially penetrating conditions occur. The Moench method was also implemented during analysis of the data and assumes that:

- The aquifer is unconfined and has an "apparent infinite extent"
- The aquifer in homogeneous and isotropic
- The well is pumped at a constant rate
- Well diameter is small, so well storage is negligible
- Drawdown is small relative to saturated thickness

This method appeared to best suit the conditions of the pump test within the intermediate and deep zones.

However, due to the geologic conditions, mainly the presence of a clay layer that separated the intermediate and deep zones, the deep zone data was also analyzed by traditional methods typically applicable to confined or leaky confined aquifers (Cooper-Jacob method and the Hantush-Jacob method).

The traditional methods of time vs. drawdown and distance vs. drawdown assume:

- The aquifer is confined and has an "apparent" infinite extent
  - The aquifer is homogeneous, isotropic, and of uniform thickness
- The well is pumped at a constant rate
- The well is fully penetrating
- Water removed from storage is discharged instantaneously with decline in head

- Well diameter is small, so well storage is negligible
- The values of u are small (rule of thumb u < 0.01)

# TEST RESULTS

The deep zone pump test data were analyzed by the Cooper & Jacob time/drawdown, the Hantush & Jacob, and Moench methods. Results from the Cooper & Jacob method (Figure 3) yielded a transmissivity of 1,900  $Ft^2/day$ , the Hantush & Jacob method (Figure 4) yielded a transmissivity of 1,310  $Ft^2/day$ , and the Moench method (Figure 5) yielded a transmissivity of 1,610  $Ft^2/day$ . Horizontal hydraulic conductivities ranged from 10.4 to 15.4 ft/day.

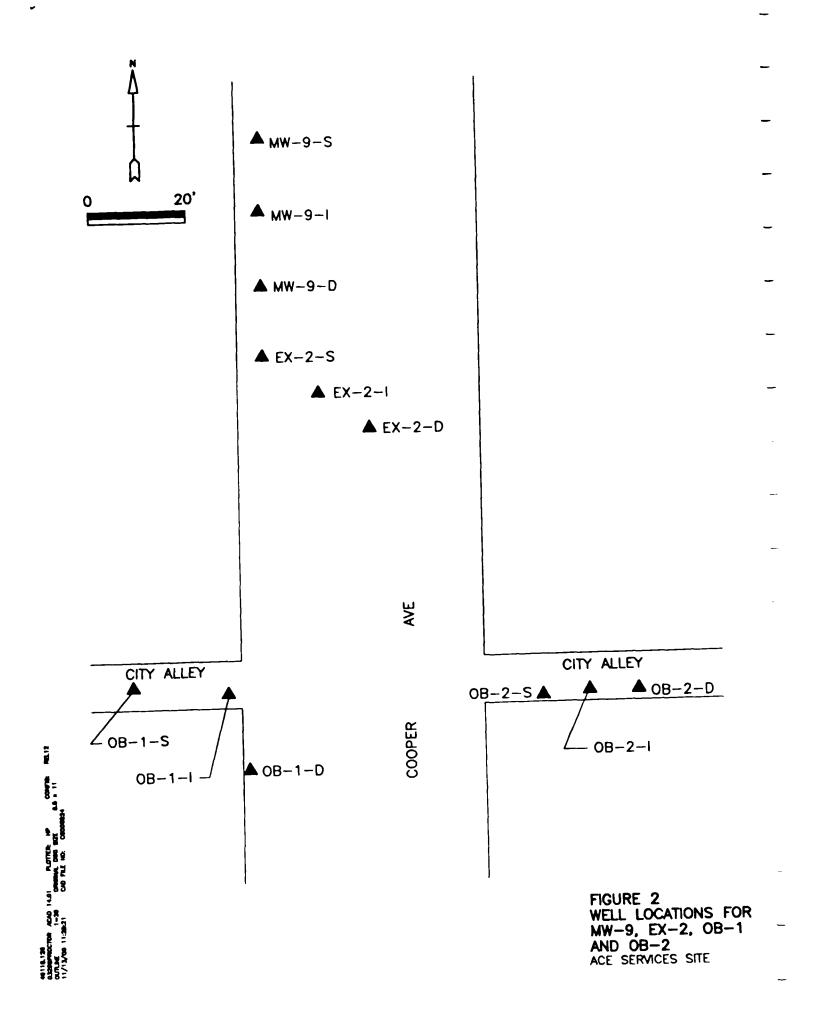

The Intermediate zone pump test data was analyzed by the Moench and Newman methods. Intermediate zone pump test data from shallow and intermediate observation wells, analyzed by the Moench method yielded transmissivities of 4,520 - 6,090 Ft<sup>2</sup>/day with storage coefficients of 0.11 to 0.20. Horizontal hydraulic conductivities ranged from 53.1 to 71.7 ft/day. Late time drawdown data from the shallow extraction well EX-2-S were used in the Moench analysis plots as illustrated in Figures 6, 7, and 8. This well was selected because it showed evidence of the delayed yield effects that were expected within the shallow zone during the test. The intermediate observation wells did not show any significant effects of delayed yield. Analysis of the late time data for the intermediate observation wells using the Neuman method, Figures 9 and 10, resulted in values of transmissivity and specific yield that were significantly lower than expected and much lower than published values for the aquifer.

The Neuman method of analysis was used for the intermediate zone pump test using shallow well drawdown data from EX -2S and MW-9S. The late-time data were graphically matched to the type curves and yielded a transmissivity of 2,940  $Ft^2/day$ . Horizontal hydraulic conductivities ranged from 17.9 to 34.6 ft/day. Neuman analysis of the intermediate observation well data yielded transmissivities of only 1,520  $Ft^2/day$ , significantly lower than expected. The values for the storage coefficient were not considered because the wells were partially penetrating.

Table 2Transmissivity Summary Table

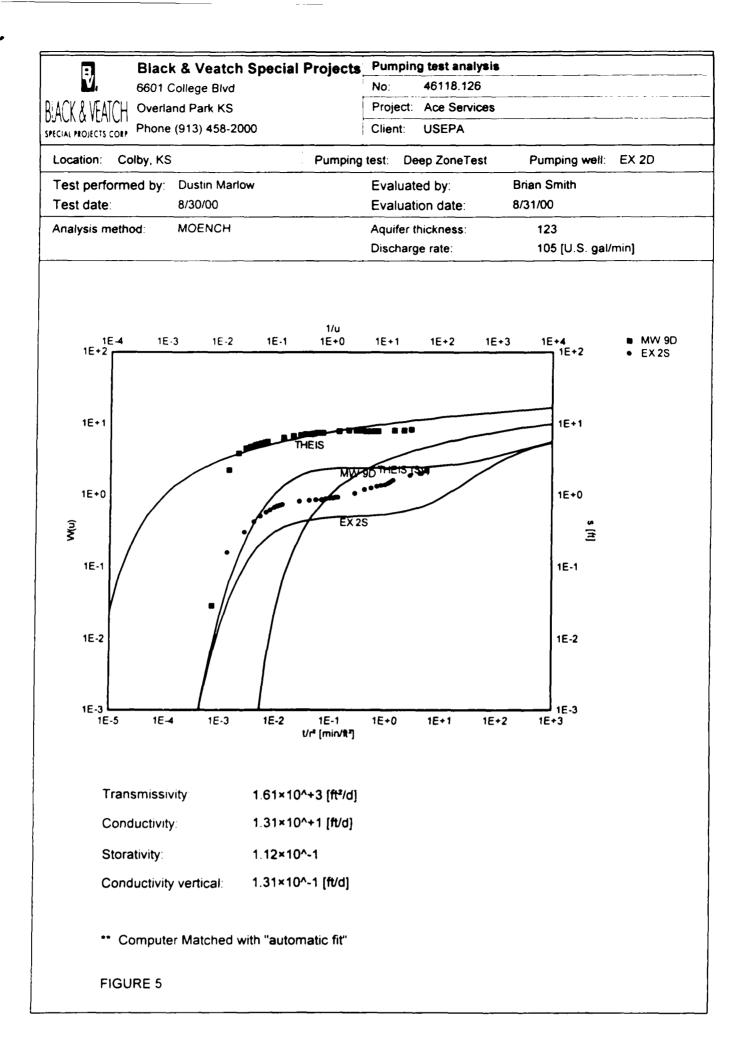

The aquifer pump tests were conducted at the Ace Services site under the assumption that there existed three distinct zones within the aquifer. However, results of the pump test analyses indicate that the High Plains aquifer at the Ace Services site may function as two distinct hydrologic zones, an upper zone (shallow and intermediate) and a lower (deep) zone. The fine grained clay-silty clay unit that separates the intermediate and deep zones appears to function as a leaky aquitard. Combining the average transmissivities of the upper (from Moench analysis) and lower zones arithmetically yields a value of approximately 6,682 Ft<sup>2</sup>/day (50,000 gpd/ft). This is consistent with published transmissivity values for this region of the High Plains Aquifer. The combined transmissivity and hydraulic conductivity values

TECHNICAL MEMORANDUM

USEPA Ace Services Ground Water Modeling Activities

BVSPC Project 46118.126 J **BVSPC File D.3** December 14, 2000

#### **INTRODUCTION**

A record of decision (ROD) for the Ace Services site was signed on May 5, 1999 stipulating an active remediation pump and treat system be installed based on a ground water model developed in 1998. Following completion of this ROD, an additional phase of investigation work was conducted in late 1999 and this new data indicates that a larger and more vertically complex plume of chromium contamination is present at the Ace Services site. To investigate this new information and provide a more accurate design basis for the pump and treat remediation system, vertically stratified pumping tests within the observed contaminated water column were performed in August 2000. These pumping tests confirm that the aquifer system exhibits a large amount of vertical heterogeneity and that the ground water contamination at the Ace Services site is vertically distributed. Therefore as part of the required modifications to the original ROD, a new ground water model was constructed to more accurately simulate the vertical flow component within the aquifer system at the site and provide input for evaluating potential remedial designs for capturing and remediating the chromium plume. The primary objectives of this new modeling effort were the following:

- Develop a ground water flow model capable of simulating the observed vertically stratified flow within the aquifer.
- Incorporate the recently collected pumping test data into the ground water flow model and calibrate this model using the pumping test results.
- Determine an effective extraction well configuration to capture the observed chromium plume.
- Determine an effective pumping rate for the selected extraction well configuration.
- Estimate the potential duration of the pump and treat remediation effort.

To accomplish these objectives, MODFLOW, a three-dimensional finite difference ground water flow model was used to simulate ground water flow and estimate the aquifer response to various ground water remediation strategies. MODPATH, a three dimensional advective particle transport program was used in combination with MODFLOW to more accurately estimate extraction well capture zones by tracking individual particles within the simulated flow field. GMS, Ground Water Modeling Software, originally developed by the Department of Defense, was utilized as a pre- and post-processor to expedite model runs and to generate ground water contour maps showing modeling results and well field configurations.

## **REGIONAL HYDROGEOLOGY**

The average saturated thickness of the High Plains aquifer in Kansas is approximately 90 feet. Water in the High Plains aquifer generally is under unconfined conditions. However, in some locations, water levels in wells completed in portions of the aquifer may rise or fall slightly in relation to the regional water table because of artesian pressure created by local confining beds. Generally the ground water gradient within the aquifer is from west to east. Water moves in response to the gradient of the water table, which typically averages between 10 to 15 feet per mile. On the basis of these average gradients and aquifer hydraulic properties, the regional velocity at which water moves through the aquifer is estimated to average about 1 foot per day. Transmissivity values within the High Plains aquifer typically range from 40,000 to 60,000 gallons per day/ft with storage coefficients ranging from 0.14 to 0.27 (Miller and Appel, U.S.G.S Ground Water Atlas, 1997).

## SITE HYDROGEOLOGY

Aquifer testing was conducted at the Ace Services site under the assumption that three distinct water bearing zones were present. However, based on the results of the pumping tests performed at the site

(Pumping Test Technical Memorandum, BVSPC, October 2000), the High Plains aquifer at the Ace Services site appears to function as two distinct hydrologic zones, an upper zone consisting of shallow and intermediate ground water and a lower zone consisting of deep ground water. A fine grained clay/silty clay unit that separates the upper and lower zones and appears to function as a leaky aquitard. Water levels recorded during the remedial investigation indicate a slightly downward vertical gradient within the aquifer surrounding the Ace Services site. Locally, ground water flows to the east-southeast at horizontal gradients ranging from 0.0022 – 0.0032 ft/ft. Continuous water level monitoring conducted prior to the pumping test activities indicates that the upper zone within the aquifer follows typical unconfined aquifer behavior. However, continuous ground water monitoring data collected from the lower zone suggests that this zone behaves as a semi-confined aquifer. This is demonstrated by observed diurnal fluctuations in hydraulic head in the deep zone wells due to the hydraulic influence of water supply wells in the vicinity of the Ace Services site. Diurnal fluctuations in hydraulic head were not observed in nested shallow and intermediate wells.

#### MODEL ASSUMPTIONS

Ground water modeling requires a set of assumptions to simplify the modeling effort in order to approximate the complexities associated with ground water flow. Simplifying some of the uncertainties of the system allows for the model to come to an accurate solution. The following assumptions were used to develop the Ace Services site ground water flow model:

- Water level data collected from nested monitoring wells at the site indicate ground water flow to the east-southeast. The data also indicate that a downward vertical gradient exists across the site. The geology within the saturated and contaminated portion of the aquifer consists of interbedded zones of sands, silty sands, gravels and a realitively consistent silty clay layer that separates the intermediate and deep water bearing zones. These hydrogeologic conditions were approximated by four model layers. Layer 1 represented the shallow zone. Layer 2 represented the intermediate zone. Layer 3 represented the silty clay leaky confining layer. Layer 4 represented the deep zone. Representing the site hydrogeology with four model layers allowed for the simulation of a vertical gradient and the stratification of aquifer properties and ground water extraction.
- Hydraulic conductivities used in the model were based on the pumping test data conducted in August, 2000. However the hydrologic data calculated from the shallow zone pumping test was determined to be unrepresentative of site conditions and was not used in the model. The small magnitudes of drawdown observed during the shallow zone test did not allow for accurate curve matching to derive an accurate solution for transmissivity. Also, the analytical solutions derived from data collected from the deep zone pump test appeared low in relation to published values. As a result, the horizontal hydraulic conductivity value from the intermediate test was used as a starting value and the values for the upper and lower layers were estimated as a percentage thereof based on lithology and well yields from the shallow and deep extraction wells. Hydraulic conductivity values of 37 ft/day (layer 1), 62 ft/day (layer 2), and 43 ft/day (layer 4) were used to simulate flow within the shallow, intermediate, and deep zones respectively. Vertical hydraulic conductivity values were estimated as K<sub>b</sub>/10. Layer 3 was simulated as a leaky-confining unit and the hydraulic conductivities of this layer were determined during model calibration. The leaky-confining unit was modeled over the entire domain of the model but may only be present in the vicinity of the site. To test the validity of these model assumptions, the model was calibrated in both steady-state and transient mode.
- The aerial and vertical extent of the contamination was assumed to be that which is defined in the technical memorandum for remedial design activities, (BVSPC, March 29, 2000). However, the actual downgradient extent of the plume and the extent of the 100 ug/L contour line representing the MCL for chromium has not been completely defined along the southern plume boundary or at the downgradient edge of the plume due to property access constraints.
- It has been assumed that proposed new nested monitoring wells installed along the southern plume boundary and at the downgradient plume edge will not show high (>500 ppb Cr) levels of contamination.
- It has been assumed that no additional source areas exist downgradient of the site.

#### **MODEL DOMAIN AND BOUNDARY CONDITIONS**

The model domain is approximately 5 miles by 4 miles with the long axis (parallel to ground water flow direction) oriented approximately 104 degrees from north. The model boundaries were extended far from the site to ensure that the boundary conditions had negligible impact on the model simulations. Figure 1 shows the model domain in relation to the Ace Services site. The model grid consists of 110 columns and 85 rows with 4 layers. Grid spacing near extraction well locations was set at 10 ft by 10 ft and expanded outward in increments of 1.5 to a maximum of 1000 feet in the x-direction and to a maximum of 500 feet in the y-direction. Constant head values were assigned at the northwest and southeast boundaries to simulate ground water entering and discharging from the model domain. No-flow boundaries were assigned to the northern and southern boundaries because ground water flow is essentially parallel to these boundaries. Ground water recharge from leakage through the overlying strata was input to the top of layer 1. A value of 0.05 in/year was assigned to the model based on published recharge data for the High Plains aquifer.

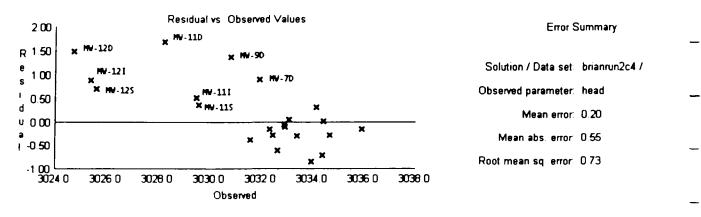

## **MODEL CALIBRATION**

The model was calibrated in two steps through both steady-state and transient simulation. In the first step, appropriate head values were input for each constant head boundary and the model was run under steadystate conditions. The modeled heads were then compared to the observed head values collected from monitoring wells at the site prior to the pump test in August 2000. Figure 2 shows the modeled simulated ground water contours with no wells pumping. Hydrogeologic parameters (constant head, recharge, horizontal and vertical hydraulic conductivity) were adjusted until the calibration error was minimal. Table 1 shows the results of the steady-state model calibration. This first part of the calibration resulted in a ground water gradient of 0.0023. Figure 3 shows a comparison between observed heads and modeled residual values (the difference between the measured heads and the modeled heads). The residual head values show that the recharge and hydraulic conductivity values (calculated from the pumping test data) used in the calibration process are representative of site conditions and did not have to be adjusted during calibration.

A trend was observed during the steady-state calibration: the modeled heads on the north and western sides of the site were lower than the observed heads and the modeled heads on the far downgradient side of the site (the labeled wells) and were significantly higher than the observed heads. The magnitude of the error appeared to be skewed by the differences in head within the deep wells (layer 4) along the eastern end of the site. One explanation might be changes in lithology, which might influence the hydraulic conductivity within and between the intermediate (layer 2) and deep (layer 4) zones of the aquifer. However, subsurface geological data does not indicate significant changes in aquifer material across the site. Another possible explanation is the position of the well screens of the monitoring wells on the western side of the site. The intermediate and deep monitoring wells at well nests at MW-2 are screened very close together and have the smallest vertical hydraulic gradient. The intermediate and deep wells at well nest MW-1 are screened at higher elevations so the wells may in fact be screened in the same hydrologic zone (intermediate). These differences in head do not significantly impact the flow model.

The second part of the calibration involved inputting calibrated steady-state head values into a transient simulation identical to the 72-hour pumping tests that were conducted within the intermediate and deep water bearing zones in August 2000. During this part of the calibration, the coefficient of storage and specific yield values were adjusted within those layers to best match the observed aquifer response during each pumping test. The transient calibration data confirm that the hydraulic conductivity and recharge values used in the model accurately simulated flow within the aquifer. Table 2 shows the results of the transient calibrations.

Table 2 Transient Calibration Results

# SENSITIVITY ANALYSIS

After the model was calibrated, a sensitivity analysis was conducted to evaluate the model uncertainty. Hydraulic conductivity and aquifer recharge were both increased and decreased by factors of 25 and 50 percent, and the residual sum of squares (difference or residual between the measured and the modeled head values squared) was calculated. The results of the sensitivity analysis are shown on Table 3. These results indicate that the calibrated model has the best match. The sensitivity results also indicate that the model is most sensitive to changes in hydraulic conductivity.

# **EXTRACTION WELLFIELD DESIGN EVALUATION**

Following calibration of the MODFLOW model, an active ground water extraction scheme was developed for containment and remediation of the contamination at and down gradient from the Ace Services site. Well locations were selected by incorporating property access considerations, position within the known extent of contamination, and pumping rate required to actively remediate the contamination. Property access was a major factor in extraction well location selection to minimize cost and property agreement delays.

Both MODFLOW and MODPATH programs were used to optimize extraction well locations and pumping rates. Ground water pumping rates were simulated at different locations within the different model layers using the calibrated steady-state heads to generate ground water contour plots for each layer. A set of optimal pumping scenarios were developed and used by the MODPATH particle tracking program to

further define extraction well positions and pumping rates. Particle travel times of 3 years were used as a benchmark when considering the well locations for active contaminant removal. The three year time period was used because most of the extraction well locations simulate capture of the edges of the 100 ug/L plume in less than 2 years. However, certain well locations require a minimum of 3 years to capture ground water from the edges of the 100 ug/L contour, indicating that it will require approximately 3 years to remove one pore volume within the area encompassed by the plume.

As outlined in the Technical Memorandum for Remedial Design (BVSPC, March, 2000), three distinct zones of contamination were identified through the sampling activities. The largest aerial extent of chromium contamination occurs within the intermediate zone of the aquifer. This zone will also require the greatest number of extraction wells to capture the contamination. The shallow zone and the deep zone will require a fewer number of extraction wells. The proposed total combined pumping rate and the proposed number of extraction wells differs significantly from the original FS modeling study due primarily to the large increase in the vertical and lateral extent of the plume.

Simulations within the shallow zone (layer 1) resulted in three optimal pumping scenarios that would sufficiently capture the maximum extent of contamination in an acceptable time frame. One limitation within the upper most portion of the aquifer is saturated thickness. Within the upper zone (layer 1) there exists only 30-35 feet of saturation. As a result, ground water extraction rates are limited to the 20 to 30 gpm range in order to maintain a steady pumping rate. These lower extraction rates limit the cone of influence generated by the extraction wells. Figures 4, 5, and 6 show the optimum well configurations and pumping rates predicted within the shallow zone of the aquifer. It should be noted however that these scenarios, simulated by extracting water from the shallow zone (layer 1), will be accomplished in the field by extraction wells screened within both the shallow and intermediate zones. The total pumping rate expected to capture and contain the shallow zone contamination is expected to be 65 - 85 gpm. It should be noted that the 25 gpm that is simulated at the PWS-8 well location may vary because the actual discharge from the upper zone during pumping at PWS-8 has not been determined.

Four optimal pumping scenarios were developed for the intermediate zone (layer 2) remediation. The intermediate zone is the most transmissive interval within the aquifer in the vicinity of the site. Figures 7, 8, 9, and 10 show the well configurations and pumping rates that most efficiently capture the contamination within the intermediate zone. A series of 5 or 6 extraction wells was used to maximize the area of capture and minimize the time required for treatment of the entire plume. The extraction well east of the plume, as shown in Figures 7, 8, and 9, is not located within the 100 ug/L contour. This additional well was simulated because of data from the residential wells indicates the presence of contamination, but the vertical distribution of the contamination in this area is not known because the residential wells are screened within multiple zones. Extraction well discharge rates vary from 35 gpm to 100 gpm depending upon the zone of capture. The predicted total discharge of 50 gpm that is simulated from the intermediate zone of PWS-8 may vary due to the lack of information on that multi-screened well. The majority of the contaminant load for the treatment plant will come from the intermediate zone.

The simulated extent of capture within the deep zone (layer 4) is illustrated in Figures 11 and 12. Pumping rates vary from 35 to 100 gpm depending upon the position within the plume. Cones of influence are much larger within this zone because it behaves as a semi-confined zone within the aquifer. Estimated total discharge expected to actively remediate the deep zone range from 185 to 300 gpm. The discharge from the lower screen zone within PWS-8 was estimated and contributes to the uncertainty of the actual pumping rates that will be required within the deep zone.

#### **EXTRACTION WELLFIELD DESIGN RECOMMENDATIONS**

The well configuration shown on Figure 13 illustrates the optimal shallow zone pumping scheme. Extraction wells EX-2S and PWS-8 have already been installed, therefore shallow wells EX-3S and EX-4S will need to be installed.

The optimal extraction well scheme for the intermediate zone is shown on Figure 14. This scheme incorporates 6 wells pumping at a combined total of 335 gpm. Wells EX-21 and PWS-8 were installed during the remedial design investigation and pumping test activities. Wells EX-11, EX-31, EX-41, and EX-51 will need to be installed in the intermediate zone with an option for a seventh well. This optional well may be installed east of EX-51 if additional analytical data indicate that the extent of the plume is further east than presently indicated.

Figure 15 shows wells EX-1D, PWS-8, EX-2D, and EX-3D pumping a total of 260 gpm for complete capture of the deep zone contamination. Well EX-1D and EX-3D will need to be installed. Wells EX-2D and PWS-8 are already installed.

The proposed configuration for all of the extraction wells is illustrated on Figure 16, assuming property access is granted for each location. Proposed extraction well design specifications are presented in Table 4. This report estimates a total extraction rate of approximately 690 gpm. At this pumping rate it is expected that one pore volume of the aquifer will be removed approximately every 3 years. However, it is common to require flushing several (3 to 5) pore volumes through contaminated media to reduce contaminant concentrations to cleanup goals. The total time to actively remediate the chromium contamination to acceptable levels is estimated to be approximately 12 years. Due to the variability within the multi-layered aquifer with respect to both the horizontal and vertical distribution of contaminants, it is recommended that the final plant design influent rate incorporate some flexibility to allow for a 15% to 20% increase in flow. Should the results of this modeling study be incorporated into a final design, 8 additional extraction wells at four different locations (2 shallow, 4 intermediate, and 2 deep) will be needed to be installed to ensure that contaminant capture is occurring and to monitor contamination reduction. The total number and final pumping rates of the extraction wells required to meet the site remediation objectives may differ from the predictions presented in this report.

Subject:

EPA Contract No. 68-W5-0004 W.A. No. 034-RDRD-07GE Responses to KDHE Review Comments for Technical Memorandum Remedial Design Sampling Activities, Ace Services Site, Colby, Kansas

Dear Mr. Stewart:

The following are responses to review comments for the Technical Memorandum Remedial Design Sampling Activities, Ace Services Site, Colby, Kansas (March 29, 2000). The comments were provided by the Kansas Department of Health and Environment (KDHE), April 18, 2000. The review comments are restated in italics, followed by responses from Black & Veatch Special Projects Corp. (BVSPC).

1. KDHE/BER requests an electronic copy of the site map when it is completed.

An electronic copy of the site map will be forwarded to KDHE when the survey is final.

2. Pages 3-5 and 3-9, Sections 3.1.5 and 3.3.2. Newly installed wells were sampled immediately after the wells were developed. The well development procedure, however, only removed "at least half as much water as was introduced during drilling". From the discussion in the report, there appears to be the potential that samples from the new wells may not be representative of aquifer conditions. Is data from the new wells consistent with the old wells? For example, consider the results from MW-8-D (89 mg/L total Cr) compared to PWS well No. 8 (1930 mg/L total Cr) which is immediately adjacent. The report should discuss the implications of the well development procedure relative to any theoretical effects on the quality of the samples.

Well development consisted of surging and pumping the well using an electric

the imagine - build company\*

Mr. Bob Stewart

BVSPC Project 46118.126 May 12, 2000

submersible pump. The temperature, pH, specific conductivity, turbidity, dissolved oxygen (DO), and oxidation reduction potential (ORP) was monitored during pumping. Pumping continued until the field parameters stabilized and the water was clear and free of fines at which time the samples were collected.

Additional water was also removed during well construction. Approximately 400 gallons of water was displaced and collected from each boring during installation of the well casing, filter packs, bentonite seal, and bentonite grout. This information will be included in the report.

This same development/sampling method was used for all newly installed wells. Analytical results of total chromium in groundwater samples ranged from non-detect to 2740 ug/L, indicating dilution of groundwater by introducing drilling fluid (potable water) was not significant and that the samples are representative of groundwater quality.

All wells will be sampled again during the final stages of the remedial design. Analytical results of the two rounds of sampling will be compared and, if necessary, extraction well locations could be relocated to accommodate changes in concentrations and limits of the plume.

3. Page 5-1, Section 5-2, last sentence. Conclusive evidence has not been gathered to show that leaching of residual chromium from the unsaturated zone to groundwater is no longer occurring. Showing that chromium concentrations in the unsaturated zone decrease with depth only shows the depths of chromium contamination in the unsaturated zone. Migration of chromium to groundwater does not occur through movement of the mass of chromium downward through the unsaturated zone, but rather by dissolution of chromium as water percolates downward to the water table. Chromium concentrations in groundwater 200 to 500 feet downgradient of Ace Services still range from 500 to 1130 mg/L. During the removal of chromium sludge in 1994, it was recognized that the bottom of the soil contamination had not been reached even after digging 20 feet below the floor of the Ace Services building (EPA Site Progress Report, July 13, 1994). If the source has been significantly reduced, then with time chromium concentrations in groundwater near the source area should diminish while higher concentrations continue to exist downgradient. Enough time may not have passed to see such a trend, however, since remediation of groundwater will not be successful without significant source reduction, further analysis should be conducted to assess whether or not the source area continues to be active.

Mr. Bob Stewart

BVSPC Project 46118.126 May 12, 2000

Ceasing discharge of wastewater and the excavation of contaminated sludge and soils has removed the primary sources of groundwater contamination. It is not evident that the remaining contaminants will migrate significantly to the groundwater.

Elevated chromium levels in the surface soil of the lagoon area was addressed when the surface soil was remediated to cleanup levels (1500 mg/kg total chromium and 500 mg/kg lead) during the 1994 removal action. A monitoring well (MW-10-P) was installed near the former lagoon and screened at a depth of 30 feet (BVSPC 1999) to evaluate the possibility of a contaminated perched groundwater zone. Well MW-10-P has been dry on every water level measurement event indicating the perched groundwater zone is no longer present.

As described in comment #6 of the Responsiveness Summary of the ROD, EPA will conduct further investigation of the subsurface soil. Initial efforts including subsurface soil sampling and installation of well MW-10-P has been performed. Additional efforts will continue up to and after the groundwater extraction program has begun. This will allow EPA to judge the effectiveness of the extraction and then determine if the soils have a continuing source impact on the groundwater quality. A decision concerning further remedial action of the soil will be made before or during the 5-year review

Further evaluation of significant leaching of contaminants from the lagoon area soils will be made by sampling groundwater from each of the three screened intervals of the Ace Recovery well. The groundwater sampling will be performed quarterly for the first year as part of the remedial action as described in the ROD or more frequently as necessary to evaluate contaminant trends in the groundwater. Analytical results from groundwater samples collected from the Ace Recovery well will identify any trends in contaminant leaching. It is estimated that the contaminant concentrations will decrease with time. In addition, well MW-10-P will be monitored to verify that the perched groundwater condition is still no longer present.

4. Figures 5-7 and 5-8. The extent of chromium contamination above the Maximum Contaminant Level (MCL) within shallow and intermediate depths of the groundwater aquifer has not been defined. The extent needs to be known to determine if the plume can be captured by the proposed extraction wells and to determine if additional receptors, such as wells R-7 and R-8, might be at risk. KDHE/BER recommends installation of additional wells

east of MW-12 to define the downgradient extent of chromium contamination. KDHE/BER also recommends installation of additional wells south of the railroad line because the direction of groundwater flow indicates that the chromium plume should be oriented in a more southeasterly direction from the source area. Most receptors to the plume are located along either side of Highway 24, which led us to position monitor wells along the same east-west directional trend. This has resulted in a picture of the plume that follows the highway, rather than the groundwater gradient. To determine if the plume will be captured by the extraction wells, the spatial distribution of the plume needs to be known. See enclosures 1 and 2 for the areas where additional wells should be located.

Current data have delineated the plume extent and concentration for the purposes of remedial design. However, to further ensure optimization of the placement of extraction wells additional monitoring wells will be installed as KDHE requests. It is proposed that two additional groundwater monitoring well nests consisting of shallow and intermediate depth wells be installed south of the railroad tracks. Proposed locations for the two well nests are illustrated on the attached figure. Final locations of the wells will be limited to property access restrictions.

If you have any questions or require any additional information, please call me at (913) 458-6583.

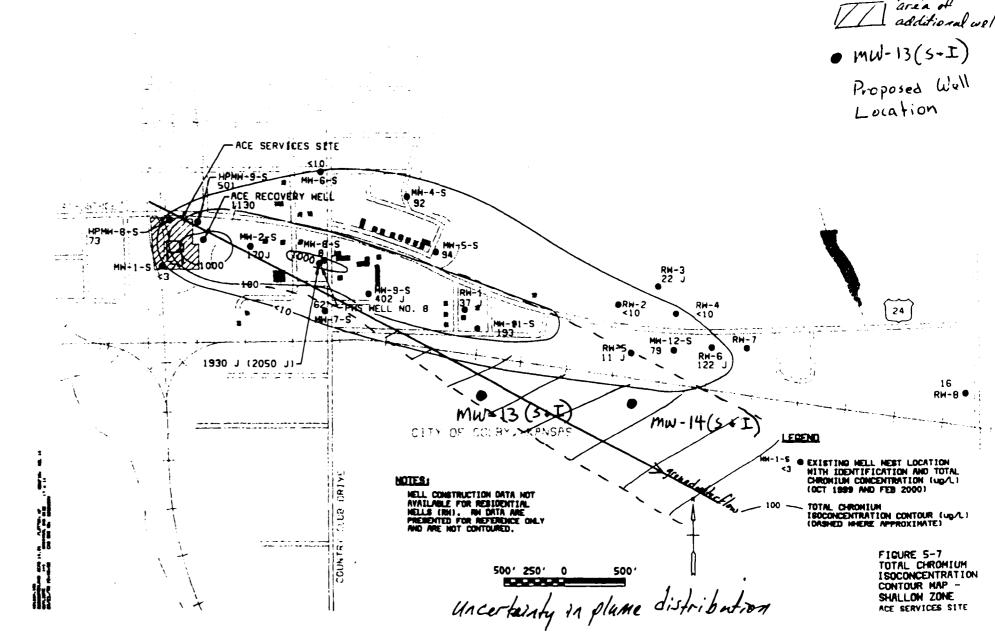

Sincerely,

BLACK & VEATCH SPECIAL PROJECTS CORP.
