

Cherry blossoms of the Japanese Yoshino variety bloom along the Tidal Basin, March 19, 2012, in Washington, DC, with the Jefferson Memorial to the rear. This season celebrates the 100-year anniversary of the gift of the cherry trees from Japan to Washington, DC. (Paul J. Richards/AFP/Getty Images)

COMP 364 - Lecture 25

March 26th, 2012

Mathieu Perreault

Python and SQLite

What we know so far

- **Database** is the main structure (only one database at a time)
- A database contains many **tables**, each with a **column structure**.
e.g. `gene_id`, `gene_name`, `gene_length` for table *genes*
- A table can contain multiple **records**, each represented by a **row**.
- We can access the different **columns** of a record to get/set the data.

Database structure

Database

table1

column1, column2

record1
<column1_value>, <column2_value>

record2
<column1_value>, <column2_value>

table2

column1, column2, column3

record1
<col1_value>, <col2_value>, <col3_value>

record2
<col1_value>, <col2_value>, <col3_value>

table3

column1, column2

record1
<column1_value>, <column2_value>

record2
<column1_value>, <column2_value>

record3
<column1_value>, <column2_value>

Getting the content from a database

- Opening the database
- View the tables in a database
- View the fields (columns) in a table
- View all the records (rows) in a table
- View *some* of the records according to some filtering rule
- Full SQLite Syntax reference: <http://www.sqlite.org/lang.html>

Creating new content in a database

- Opening the database
- Create a table in the database
- Insert records in the database
- Update records in the database
- Delete records according to a specific condition
- Delete tables
- Full SQLite Syntax reference: <http://www.sqlite.org/lang.html>

A word about PRIMARY KEY

- A primary key in a table ensures that the specified column will have a distinct value for each record
- Only one primary key is allowed **per table**.
- It could be an INTEGER, TEXT, etc.
- When specifying a column definition (such as when creating a table), just add PRIMARY KEY:

```
CREATE TABLE grades (student_id INTEGER PRIMARY KEY, grade REAL);
```

- PRIMARY KEY AUTOINCREMENT will increase the key for you, no need to specifically insert it.

Default value

- You can also specify default values if you have special needs
- You simply need to add it to the column definition (for example, when creating a table)
- For example, specifying a default value of 100.0

```
CREATE TABLE grades (student_id INTEGER PRIMARY KEY, grade REAL DEFAULT 100.0);
```

Database structure

my_database

genes

gene_id, gene_name

record1

1, "E.coli"

record2

2, "BRCA"

plates

plate_id, date, humidity

record1

50, 2012-03-16, 0.65

record2

51, 2012-03-16, 0.70

microarray

read_id, **gene_id**, amplitude

record1

1, 1, 0.50

record2

2, 2, 0.65

record3

3, 2, 0.80

Joined at the hip (or: JOIN clauses)

- Sometimes you will have tables that complement other tables
- It's one advantage of SQLite, no need to store redundant information
 - No need to store `gene_name` every time you make a measurement on the gene!
- To **query** for this information, we will need to tell SQLite that two fields from different tables are really talking about the same thing!
 - Not sufficient to name them the same (e.g. `gene_id`)

Joined at the hip (or: JOIN clauses)

- The JOIN clause can be added to the source:

- `SELECT [columns] FROM table1 JOIN table2 ON table1.field_foo=table2.field_bar WHERE [condition];`

- This says: “I’m selecting records in table 1, but bring in extra information about those records from table 2”

- The extra information can be used in the WHERE clause:

```
SELECT * FROM genes JOIN microarray ON genes.gene_id=microarray.gene_id WHERE microarray.amplitude>0.6;
```

- Can augment the results:

```
SELECT microarray.amplitude, genes.gene_name FROM genes JOIN microarray ON genes.gene_id=microarray.gene_id;
```

Today: SQLite in Python

- SQLite is included in Python (how convenient!)
- You can write code that interacts with SQLite.
- The power of Python, combined with SQLite, makes for a great program.

SQLite in Python

- Four things need to happen for Python to interact with SQLite

- Import the sqlite module

```
import sqlite3
```

- Connect to the database (or create one) with a given name

```
connection = sqlite3.connect('database.sql')
```

- Get a cursor to the database:

```
cursor = connection.cursor()
```

- Execute queries on the cursor:

```
cursor.execute('SELECT * FROM ...')
```

SQLite in Python

- Once a query has been executed on the cursor, some data might be available, e.g. if you made a SELECT query.
- `cursor.fetchone()` will return one record at a time.
- `cursor.fetchall()` will return all matching records at once in a Python list.
- You have to test if the result is `None` before using it.
- **Don't forget to call `connection.commit()` to commit the changes!**
