Madariaga virus (MADV) is the new designation for the South American strains of Eastern Equine Encephalitis virus (EEEV). The first outbreak was documented in 2010 in Darien, Panamá in an area that is endemic for the Venezuelan Equine Encephalitis virus (VEEV). VEEV and other arboviruses are endemic in equines in Costa Rica. Several cases of equine encephalomyelitis are reported annually in Ostional, Guanacaste at the northwest part of the country. This region is composed by dry forest and multiple cattle ranches. Based on previous reports of the disease in this area, eight different locations were selected for field sample collection during two different tropical weather seasons (rainy and dry season). Birds were sampled in order to identify their potential role as arboviral reservoirs. Mist netting was performed at peridomiciliary, forest, and stockyard areas at dusk and dawn. Birds were euthanized, organs were collected (heart, lung, liver, spleen, kidney, central nervous system, reproductive system, eye, proventriculus, intestine, stifle joint), and a complete post-mortem analysis was done for histopathological and molecular analysis. A RT-PCR for flavivirus and alphavirus was performed on individual and pooled organs. One *Turdus grayi* from ranch "D" was positive for alphavirus (NSP4 region, 210 pb product). Phylogenetic analysis showed a 97% identity with the MADV isolated in Panamá in 2010. Histopathological analysis revealed multifocal inflammatory aggregates composed predominantly by lymphocytes, few histiocytes, plasma cells, and scattered heterophils in myocardium, liver, kidney and lung. Additionally, lymphoid hyperplasia was observed. This is the first report of MADV in Costa Rica. Further sampling will be conducted in order to characterize a putative zoonotic/epizootic virus cycle.

Stanford, CA, United States, [5]St George's University School of Medicine, St. George, Grenada, [6]Ministry of Health, St. George's, Grenada, [7]University of Colorado School of Medicine, Aurora, CO, United States

Chikungunya virus (CHIKV) is a rapidly re-emerging global pathogen causing both acute and chronic disabling illness. There is currently no vaccine. An RNA virus within the family *Togaviridae*, CHIKV is transmitted to humans by the mosquito vector *Aedes aegypti* and related species. *A. aegypti* is the same species that transmits Dengue and Zika viruses. CHIKV exists in three phylogenetically distinct groups: West Africa and East, Central, and Southern Africa (ECSA), and Asian genotypes. The rapid spread of CHIKV has been driven by the expanding mosquito vector populations as a result of urbanization and climate change as well as increased global travel. CHIKV was introduced into the Caribbean in 2013, which led to an explosive outbreak in Grenada. During this outbreak a total of 143 CHIKV samples from acute case symptomatic patients were collected and confirmed positive with PCR. At the California Academy of Sciences, RNA was extracted from CHIKV positive sera and Illumina Miseq sequencing was performed yielding 17 complete genomes. Despite CHIKV positive sera, a handful of samples illuminated an underlying-and undetected-dengue virus (DENV) co-infection. These DENV co-infections yielded near complete genomes of DENV serotypes 1-3, indicating co-circulation of both CHIKV and DENV in a single epidemic season. Phylogenetic analyses were performed using maximum likelihood methods. All of the CHIKV Grenada samples form a monophyletic group, suggesting a single main introduction into Grenada. By employing phylogenetic and whole-genome analyses of CHIKV we reveal a deeper understanding of evolutionary patterns, phylodynamics and epidemic trends, as well as public health challenges.

Plasma leakage, which can lead to hypovolemic shock and potentially fatal complications, is a pathogenic hallmark of severe dengue disease. Previously, we demonstrated that dengue virus (DENV) non-structural protein 1 (NS1) directly triggers endothelial permeability and vascular leak. We also showed that NS1-immune serum and anti-NS1 monoclonal antibodies (mAbs) block NS1-induced endothelial dysfunction of human endothelial cells *in vitro* and prevent NS1-mediated lethality *in vivo*. Recent studies identified NS1 immunodominant regions and established that antibodies against the NS1 wing domain can inhibit DENV infection and prevent DENV-induced mortality in mice. However, the molecular mechanisms by which antibodies prevent NS1 pathogenesis are not fully understood. Here, we studied the relative contribution of DENV NS1 domains to NS1-induced pathogenesis *in vitro* and whether antibodies against specific NS1 regions are associated with protective responses *in vivo*. We found that the DENV NS1 hexamer, but not individual domains, increase permeability of human pulmonary microvascular endothelial cells (HPMEC). Further, only full-length DENV NS1 was able to bind to endothelial cells and trigger disruption of the endothelial glycocalyx. We also found that sera against the wing domain partially block NS1-induced endothelial hyperpermeability, whereas sera against the β-ladder and tip domains did not. In ongoing experiments, we are assessing a panel of anti-NS1 mAbs for their ability to block NS1 binding to endothelial cells and to prevent endothelial dysfunction *in vitro*. Initial results suggest that only parts of each domain are critical for NS1 blockade, as a number of mAbs with the same NS1 domain specificity differ in their capacity to abrogate NS1 binding and/or endothelial permeability. Finally, blocking antibodies are being evaluated for their capacity to prevent vascular leak in a mouse model. Together, these studies provide a comprehensive assessment of the specificity, mechanism of action and efficacy of anti-NS1 humoral responses and identify critical regions that can be targeted to block NS1-mediated pathogenesis.

1605

UNRECOGNIZED DENGUE AND CHIKUNGUNYA HUMAN TRANSMISSION IN WESTERN AND COASTAL KENYA

A. Desiree LaBeaud[1], Francis M. Mutuku[2], Elysse N. Grossi-Soyster[1], David M. Vu[1], Amy R. Krystosik[1], Justin Lee[1], Dunstan Mukoko[3], Charles H. King[4], Bryson A. Ndenga[5]

[1]Stanford University School of Medicine, Stanford, CA, United States, [2]Department of Environmental Health and Sciences, Technical University of Mombasa, Mombasa, Kenya, [3]Ministry of Health, Nairobi, Kenya, [4]Case Western Reserve University, Center for Global Health and Diseases, Cleveland, OH, United States, [5]Kenya Medical Research Institute, Kisumu, Kenya

Dengue (DENV) and chikungunya (CHIKV) viruses cause human disease in Kenya, but remain poorly controlled and under-recognized. To understand the true burden of exposure and resultant disease from these important arboviruses, our objective was to determine the distribution of CHIKV and DENV cases among children in Kenya. Two cohorts of children (Jan 2014-present) were enrolled at four Kenyan study sites (rural west, rural coast, urban west, urban coast): a healthy child cohort followed every six months to document asymptomatic CHIKV and/or DENV infections via IgG ELISA testing, and an acutely febrile child cohort followed to convalescence to document symptomatic disease via RT-PCR and IgG ELISA. Questionnaire data were collected to describe demography, socioeconomic status (SES), and household environment. 3% (121/4263) of febrile disease was attributable to CHIKV and 4% (173/4592) to DENV. Approximately 6% (393/6980) of febrile illness was attributable to either virus. We detected unrecognized outbreaks of both CHIKV and DENV and alerted Ministry of Health officials to promote control policy. The majority of children with single infections presented with mild syndromes and fully recovered by one month; however, those with malaria co-infections (158/4478) were sicker and recovered more slowly. Among healthy cohorts (500 children per site), asymptomatic infections were rare: only 8 asymptomatic CHIKV seroconversions (0.3%) and 9 DENV seroconversions were noted (0.3%) over four years of active surveillance. Exposure to CHIKV or DENV was associated with age, SES, mosquito exposure and avoidance behaviors, and hygiene and wealth indices. Continued misdiagnosis as malaria and the slow uptake of policies to prevent arboviral disease affect child health in Kenya. Better recognition of CHIKV and DENV in the health care setting, coupled with targeted vector control interventions at the local level, could dramatically decrease the impact of these enduring disease threats.

1606

COULD VIRAL CO-INFECTION OF MOSQUITOES IMPACT VECTOR CONTROL? A NEW DEVELOPMENT FOR BIOLOGICAL VECTOR CONTROL

Avian White

East Carolina University, Washington, NC, United States

Could Viral Co-infection of Mosquitoes Impact Vector Control? A New Development for Biological Vector Control Mosquito-borne diseases are responsible for several million deaths and hundreds of millions of cases of human illness yearly. Mosquitoes can be vectors of many different pathogens that may cause a variety of human and veterinary illnesses (e.g. dengue, Zika, malaria and chikungunya). Many of these arboviruses may be found circulating in the same region. Dengue virus, one of the most important arboviruses in terms of public health, circulates in in Africa, Asia, the Americas, and the Pacific and is primarily found in the tropics and the sub-tropics. This is the same footprint of many other viruses, such as Zika and chikungunya. In addition to having the same

spatial distributions, the viruses are also carried by the same vector: *Aedes aegypti* and *Aedes albopictus*. This overlap in regions and vectors could possibly lead to co-infection in a human subject. In addition to being vectors to arthropod-borne viruses that can cause disease, mosquitoes are also hosts to viruses that are not transmitted to vertebrates, that do not cause human disease. In Espirito Santo, Brazil, a biological sample containing DENV-2 was analyzed, leading to the discovery of a new virus aptly named, Espirito Santo Virus (ESV). Preliminary studies on this virus showed the virus replicates in C6/36 (Ae. albopictus) insect cells but not Vero (African green monkey kidney; mammalian cells). In addition, to these studies ESV has initially been shown reduce titer values of DENV-2, when co-infected simultaneously. Current preliminary studies have also shown a reduction in infection rates of DENV-2 of ESV infected mosquitoes. Ongoing research into the relationship of co-infection of ESV-DENV could have dramatic impacts of vector control. The manipulation of mosquitoes to reduce their vector competence, could open new avenues of vector control. Our research aims to build on these preliminary results and study the relationship of how these two viruses affect each other during co-infection.

1607

CONTRIBUTION OF TYPE-SPECIFIC VERSUS CROSS-REACTIVE ANTIBODIES TO NEUTRALIZATION FOLLOWING REPEAT DENGUE VIRUS INFECTIONS

Daniela V. Andrade[1], Ciara Gimblet-Ochieng[2], Paulina Andrade[1], Magelda Montoya[1], Leah C. Katzelnick[1], Sandra Henein[2], Aravinda de Silva[2], Eva Harris[1]

[1]Division of Infectious Diseases and Vaccinology, School of Public Health, University of California Berkeley, Berkeley, CA, United States, [2]Division of Infectious Diseases, University of North Carolina, Chapel Hill, NC, United States

The four dengue virus (DENV) serotypes can cause repeat infections, each time with a new serotype. While primary infection generates life-long neutralizing antibodies to the infecting serotype, secondary DENV infections elicit cross-neutralizing antibodies to two or more serotypes. As recent vaccine trial results and natural DENV infection studies highlight, the quality of the neutralizing response is a complex matter that needs further investigation. One important question to be addressed is whether neutralizing antibodies after secondary infection target cross-reactive epitopes conserved across serotypes or epitopes specific to each serotype previously encountered. Antibody depletion methods developed previously provide a tool to evaluate the sequence of DENV infections and the contribution of type-specific (TS) versus cross-reactive antibodies to neutralization by polyclonal sera. In this study, we analyzed sera from subjects enrolled in a long-term prospective pediatric cohort study in Nicaragua, which allowed us to evaluate repeat infections in individuals with a well-characterized history of first, second and in some cases third DENV infections. Using depletion of antibody subpopulations, we found that after a first infection, a substantial proportion of TS antibodies contribute to the neutralizing response, and after a second infection, the cross-reactive response dominates. In some individuals, TS antibodies to both infecting serotypes can be detected. Moreover, we simultaneously interrogated B cell serotype-specificity and cross-reactivity in the same individuals via the Quad-Color FluoroSpot (QFC) assay, which enables analysis of the memory B cell response at a single-cell level. This unique set of samples from individuals with repeat infections in a dengue-endemic area allows dissection of both antibody and B cell responses at the individual level and in an epidemiological context. Altogether, this study advances our understanding of natural DENV infections and has direct implications for vaccine design.

1608

COMPREHENSIVE MUTAGENESIS OF DENGUE VIRUS ENVELOPE PROTEINS TO MAP ANTIBODY EPITOPES AND IDENTIFY RESIDES ESSENTIAL FOR FUNCTION

Edgar Davidson, Tabb Sullivan, Jen M. Pfaff, Srikar Reddy, Benjamin J. Doranz

Integral Molecular, Inc., Philadelphia, PA, United States

To characterize the immune response to dengue virus (DENV) infection, we have epitope mapped 200 anti-DENV monoclonal antibodies (MAbs), using high-throughput, rapid screens of MAb binding to DENV prM/E comprehensive mutation libraries for all four DENV serotypes, 3,380 mutations in total. Each library of individual mutant expression plasmids was transfected into human cells to achieve native protein expression and folding, and immunoreactivity of MAbs to each individual prM/E variant was quantified by high-throughput flow cytometry. The epitopes obtained were both conformational (including quaternary) and non-conformational, were spread across prM and E domains I-III, and many have been correlated with their abilities to protect against DENV infection. A number of anti-DENV MAbs cross-reacted with ZIKV prM/E, predominantly within the fusion loop but also within Domain II of the E protein, identifying critical immunogenic residues shared by DENV and ZIKV. We have also produced DENV virions from all four DENV mutation libraries using a previously developed DENV reporter virus particle (RVP) system, allowing us to screen each individual DENV Env variant protein for DENV particle budding and infectivity. For DENV3, we identified residues whose mutation eliminated virus infectivity but did not impact E protein expression, antigenicity, virion assembly, or particle budding. We identified variants that showed increased DENV virion budding, up to 5-fold above wild-type, indicating the ability to engineer highly expressed, non-infectious DENV variants for use in vaccine design. To identify uncharacterized DENV cellular receptors we assayed wild-type DENV RVP infectivity in non-permissive cells expressing our membrane proteome array (MPA) of 5,300 unique human membrane proteins. This has identified candidate membrane proteins that enable DENV infectivity. We have identified neutralizing epitopes in DENV prM/E and specific sites that are critical for DENV infectivity, providing new targets and opportunities for vaccine development.

QUALITY OF THE ANTIBODY RESPONSE INDUCED BY A LIVE ATTENUATED TETRAVALENT DENGUE VACCINE IN NAIVE AND DENGUE EXPOSED INDIVIDUALS

Laura J. White[1], Mark Stoops[1], Jesica Swanstrom[1], Ellen Young[1], Swati Mukherjee[2], Hansi Dean[2], Ralph S. Baric[1], Aravinda M. de Silva[1]

[1]University of North Carolina at Chapel Hill, Chapel Hill, NC, United States, [2]Takeda Vaccines Inc., Cambridge, MA, United States

Dengue is the most prevalent arthropod-borne viral disease in humans. Cocirculation of 4 dengue virus (DENV) serotypes and increased risk of severe disease after a secondary DENV infection have made the development of a dengue vaccine especially challenging. Reports from clinical trials of a leading tetravalent vaccine candidate suggest that qualitative as well as quantitative aspects of antibodies, may play an important role in determining protection. Humoral immunity to DENV infection in humans is characterized by both serotype-specific (TS) and cross-reactive (CR) neutralizing antibodies (NAbs). While TS NAbs have been linked to long protective immunity after primary infection with one serotype, CR NAbs seem to provide broad protection to serotypes not previously encountered, after secondary infections. The relative role of TS and CR NAbs induced after simultaneous administration of 4 DENV serotypes in a tetravalent vaccine is not well understood and may vary depending on the history of previous DENV infections. Takeda Vaccines Inc. has developed a tetravalent live-attenuated dengue vaccine (TDV)

currently in phase 3 clinical trials. To determine the levels of TS and CR NAbs to each serotype induced by TDV, we depleted specific populations of Abs from TDV-immune sera, either reactive to the homologous or the heterologous serotype, and measured the impact on neutralization. We found that the proportion of TS and CR NAbs varied among vaccine recipients and among serotypes. We also used competition assays with human monoclonal Abs and neutralization assays with recombinant chimeric DENVs to map the epitopes targeted by TDV-induced TS NAbs. We will discuss the implications of our results for evaluating vaccine performance and identifying correlates of protection.

1610

PRE-EXISTING T CELL SUBSETS AND THEIR ASSOCIATION WITH SUBSEQUENT SUBCLINICAL VERSUS SYMPTOMATIC DENGUE INFECTION

Heather Friberg[1], Anuja Mathew[2], Kathryn B. Anderson[3], Damon Ellison[4], Louis R. Macareo[4], Timothy Endy[5], Richard G. Jarman[1], Alan L. Rothman[2], Jeffrey R. Currier[1]

[1]Walter Reed Army Institute of Research, Silver Spring, MD, United States, [2]Institute for Immunology and Informatics, University of Rhode Island, Providence, RI, United States, [3]Department of Medicine, University of Minnesota, Minneapolis, MN, United States, [4]Armed Forces Research Institute of Medical Sciences, Bangkok, Thailand, [5]State University of New York at Syracuse, Syracuse, NY, United States

Dengue is an ongoing global epidemic, with increasing co-circulation of the four virus types (DENV-1-4). As more severe dengue disease is associated with secondary heterologous infection, pre-existing immunity to at least one DENV type is thought to influence the outcome of subsequent infection. Through a school-based cohort study of Thai children in grades 1-6, we defined symptomatic and subclinical DENV infections based on seroconversions that were or were not associated with acute febrile illnesses, respectively. Previous data from this cohort suggested that higher levels of pre-existing IFNγ-producing T cells positively correlated with subsequent subclinical infection. A separate study of patients from Vietnam suggested that a higher ratio of T regulatory to T effector cells correlated with milder disease. These data support the notion that the balance of different T cell subsets influences the clinical outcome of DENV infection. To investigate the contribution of different T cell subsets to the outcome of subsequent DENV infection, we used a 13-color flow cytometry panel to analyze the production of IFNγ, TNFα, IL-4, IL-10, IL-17A, IL-17F, IL-21, and IL-22 after overnight stimulation of PBMC collected prior to a documented DENV infection. We studied samples from 20 subjects with subsequent subclinical DENV infections and 20 subjects with subsequent symptomatic DENV infections. We stratified the data based on clinical outcome and compared the frequencies of various CD4+ and CD8+ T cell subsets. The data suggest that greater diversity in cytokine production is associated with subsequent subclinical outcome. These findings extend prior observations on T cells in dengue to additional T cell subsets, and lend further support to a role for T cells in shaping the outcome of DENV infection.

1611

DTK-DENGUE: A NEW AGENT-BASED MODEL OF DENGUE VIRUS TRANSMISSION DYNAMICS

James Soda[1], Sean M. Moore[1], Guido España[1], Jonathan Bloedow[2], Benoît Raybaud[2], Benjamin M. Althouse[2], Michael A. Johansson[3], Edward A. Wenger[2], Philip A. Welkhoff[4], Alex Perkins[1], Quirine A. ten Bosch[5]

[1]University of Notre Dame, Notre Dame, IN, United States, [2]Institute for Disease Modeling, Bellevue, WA, United States, [3]Centers for Disease Control and Prevention, Division of Vector-Borne Diseases, San Juan, PR, United States, [4]Bill & Melinda Gates Foundation, Seattle, WA, United States, [5]Institut Pasteur, Paris, France

Dengue is a mosquito-borne viral disease that exerts a growing impact on global health and presents a formidable challenge for public health officials, in part because many factors related to its transmission are difficult to observe and measure (e.g., vector population dynamics and number of inapparent infections). Agent-based models (ABMs) can explicitly represent these factors and can be calibrated to empirical data to provide insight about the dynamics of both observed and unobserved variables. Disease Transmission Kernel-Dengue (DTK-Dengue) is an ABM for dengue virus (DENV) transmission that extends the Institute for Disease Modeling's Epidemiological Modeling Disease Transmission Kernel (EMOD-DTK). DTK-Dengue includes three major modifications to EMOD-DTK: 1) it incorporates the influence of climatic variables on *Aedes aegypti* mosquito population dynamics, 2) it modifies adult vector activity to reflect *Ae. aegypti* behavior, and 3) it explicitly includes all four DENV serotypes, including their effects on human immunity and rates of symptomatic disease. Although ABMs such as DTK-Dengue are capable of representing a variety of observed and unobserved variables, little is known about the relative contributions of different data types from routine surveillance systems for calibrating such models. We calibrated DTK-Dengue with three complementary datasets from San Juan, Puerto Rico in 2007: the monthly incidence, the monthly number of cases by serotype, and the age distribution of cases. We ran seven calibrations, each incorporating one possible combination of datasets into the model likelihood. We evaluated the fit of the model to all data types, regardless of whether they were used in the calibration, and compared simulated output of mosquito dynamics to trap data, which is not routinely collected by surveillance systems and was thus withheld from the calibration process. These results provide insight into the relative importance of different types of commonly collected data for calibrating ABMs of DENV transmission and how the inclusion of these types influences predictions of observed and unobserved variables.

1612

SURVEILLANCE OF DENGUE VIRUS INFECTION IN NEPAL IN 2015

Melanie D. McCauley[1], Krishna Das Manandhar[2], Birendra Gupta[2], Simona Zompi[3], October Sessions[4], Sujan Shresta[5]

[1]University of California, San Diego, San Diego, CA, United States, [2]Tribhuvan University, Kathmandu, Nepal, [3]Karius, Inc, Redwood City, CA, United States, [4]Duke-National University of Singapore Medical School, Singapore, Singapore, [5]La Jolla Institute for Allergy and Immunology, San Diego, CA, United States

Dengue virus (DENV) is estimated to infect 390 million people each year. Of that, Asian countries account for 70% of cases. The first case of DENV in Nepal was documented in 2004; since then all four serotypes (DENV 1-4) have been documented in most of the southern tropical zone and as far north as the temperate Kathmandu Valley. We set out to study circulating DENV in Nepal in 2015. Patients were recruited from local hospitals who presented with dengue-like signs and symptoms. DENV IgM and IgG ELISA, DENV NS1 ELISA and DENV RT-PCR were performed on each patient and they were classified by likely primary infection, likely secondary infection, or negative. Select samples were tested by neutralization assay to assess any existing cross-protective antibody levels. Of 91 patients tested, 93% presented with fever and 86% with myalgia. Surprisingly, no patients were noted to have rash. Eight percent of patients had thrombocytopenia less than 50 x10^3/μL. Nineteen patients were found to have likely primary DENV and 5 were found to have likely secondary disease. No convalescent serum was available for comparison due to the single time point blood collection. Six patients were found to have positive RT-PCR results. Two of these patients were found to have DENV-2 serotype and both serum samples were cultured on mosquito C6/36 cell lines. Full-length genome sequencing was performed directly from sera and on the viral isolates after amplification in C6/36 cells. This is the first known full-length sequence of DENV circulating in Nepal to date. Nepal, with its

90 ethnic groups, is a unique ecologic niche where most adults have no pre-existing immunity to DENV and it circulates in a population that has been immunized against the related flavivirus, Japanese Encephalitis virus. It is a unique ecologic niche also in that it rises in elevation from 50 m to the highest point on Earth (8,848 m) within the span of 200 km. This could serve as a model to study transmission dynamics from subtropical to temperate regions. Data from this population could significantly contribute to our knowledge about DENV-host interactions and inform ongoing therapeutic and vaccine development efforts.

1613

CHARACTERIZATION OF SERA FROM DENGUE INACTIVATED VACCINE PRIMED VOLUNTEERS THAT HAD IMPROVED NEUTRALIZING ANTIBODY RESPONSES AFTER LIVE ATTENUATED DENGUE VACCINE BOOSTING

Gregory D. Gromowski, Caitlin H. Kuklis, Qiong Chen, David A. Barvir, Rafael De La Barrera, Tao Li, Wiriya Rutvisuttinunt, Michael K. McCracken, Kenneth H. Eckels, Leyi Lin, Michael A. Koren, Richard G. Jarman

Walter Reed Army Institute of Research, Silver Spring, MD, United States

A previous clinical study evaluated heterologous vaccine prime-boost regimens that consisted of a formalin inactivated dengue virus (DENV) vaccine (DPIV) prime on day 0 followed by a live attenuated DENV vaccine (TDENV) boost at 1 month (0,1 group) or 6 months (0,6 group). The 0,6 group had significantly higher neutralizing antibody (NAb) titers than the 0,1 group, and both groups elicited significantly higher NAb titers compared to unprimed volunteers given TDENV. To better understand the DPIV-primed immune profile that mediated these improved responses, we characterized sera collected on the day of TDENV booster vaccination. The NAb titers to DENV 1-4 were very low or undetectable for volunteers in both groups. The levels of DENV 1, 3, and 4 virion-reactive IgG were relatively high for the 0,1 group (mean titers >1,000), but had waned significantly for the 0,6 group. Surprisingly, volunteers in both groups had very low levels of DENV-2 reactive IgG. The DENV-2 vaccine virus was the dominant replicating component of TDENV so we also measured DENV-2 antibody dependent enhancement (ADE) *in vitro*. All subjects in the 0,1 group had detectable DENV-2 ADE curves, whereas most of the ADE curves for the 0,6 group had waned below the assay limit of detection (<1:40 dilution of serum). The magnitude of observed viremias in the 0,1 and 0,6 groups were not significantly different from unprimed volunteers that received TDENV. However, we observed that a higher proportion of subjects in the 0,6 group had detectable DENV-2 viremia (46%) compared to those in the 0,1 and unprimed groups (17% and 23%, respectively). Therefore, it is possible that waning levels of DPIV-elicited, DENV-reactive antibody improved immunogenicity of the TDENV booster vaccination in the 0,6 group by increasing vaccine virus infectivity through an ADE mechanism. However, this does not appear to explain the improved immunogenicity of the 0,1 group relative to unprimed volunteers and indicates that other immunological mechanisms might be involved.

1614

SAFETY, EFFICACY AND IMMUNOGENICITY OF DENGUE VACCINES: SYSTEMATIC REVIEW AND NETWORK META ANALYSIS OF RANDOMIZED CONTROLLED TRIALS

Nourin Ali Sherif[1], **Zaheer Ahmad Qureshi**[2], Mina Fransawy Alkomos[3], Ahmed Mohammed Alhusseiny[1], Khaled Mosaad Elhusseiny[4], Islam Ashraf Mohyeldin[5], Abdelrahman Awad Zakzouk[6], Yasmien Sherif Morsy[7], Mohamed Ashraf Mokhtar[8], Mohamed El Sayed Farrag[9], Nguyen Tien Huy[10]

Dengue virus is a global health problem. Tetravalent Dengue Vaccine (CYD-TDV) was the first vaccine to gain regulatory approval to try and address this problem. There is an urgent need for an effective and safe dengue vaccine to reduce morbidity and mortality in this high-risk population given the lack of specific treatment at present. A safe vaccine that protects against Dengue virus diseases is a global health priority. This review and network meta-analysis aimed to summarize all available evidence on the efficacy, safety, and immunogenicity of four serotypes of all available types of dengue vaccines. The data is gathered from randomized controlled clinical trial from 13 databases. The Protocol was registered at PROSPERO with the registration number CRD42016052578. Studies that reported the efficacy and immunogenicity of vaccines in the prevention of dengue virus infection and effects on the severity of the disease were included in this review with no restriction to language. Data was extracted by three independent authors. Data were analyzed by R software. Out of 518 studies identified by the electronic and manual search, 44 studies were included in our systematic review and network meta-analysis. Vaccines used were CYD-TDV, TDV, AvP TDV, TDENV PIV, TDEN F17, TDEN F19, TV003-TV005, WRAIR& GSK vaccine DEN1, DEN2 and DEN4 versus controls which were placebo or other vaccines such as meningococcal polysaccharide A+C, typhoid VI polysaccharides, varicella etc. Regarding risk ratio (RR) of injection site swelling, arthralgia, and fatigue in vaccine groups; results were insignificant in network meta-analysis in contrast to control group. However, in CYD-TDV and AvP TDV groups, the headache was significantly in contrast to controls RR=1.23 95%CI (1.06-1.43) and 18.45 95%CI (1.21 - 281.98) respectively. Seropositive conversion against serotype 1 was significantly higher in most of the vaccine groups in contrast to control. *We expect to find safety, efficacy, and immunogenicity of vaccines in the prevention of dengue virus infection, and effects on the severity of the disease as we complete the analysis of the study.*

1615

COST-EFFECTIVENESS OF DENGVAXIA VACCINATION OF PEOPLE WITH PRIOR DENGUE VIRUS EXPOSURE IN TEN LATIN AMERICAN AND ASIAN COUNTRIES

Yutong Yao, Guido España, Alex Perkins

University of Notre Dame, South Bend, IN, United States

As of March 2018, the Dengvaxia vaccine for dengue from Sanofi Pasteur has been registered in 20 countries in Latin America and Asia. In light of recently announced safety concerns for people with no prior dengue virus exposure, the World Health Organization revised its position on this vaccine to recommend that it only be used in people with prior dengue virus exposure. To date, no studies have estimated the public health impact and cost-effectiveness of Dengvaxia when applied only to people with prior dengue exposure. To provide such an assessment, we used a computational model of dengue virus transmission to simulate the impact of routine vaccination programs under various ranges of transmission intensity and with screening tests of varied sensitivity and specificity. We also simulated different combinations of routine vaccination at different ages and catch-up campaigns with different age ranges and coverages. This study analyzed and compared the cost-effectiveness of screening-based vaccination targeted at nine-year-old children and of an intervention with various catch-up cohorts based in ten countries across Asia and Latin America. We applied the simulated infections derived from the model to the cost-effectiveness analysis framework provided by WHO. The work also relied on literature for local vaccine cost and cost per DALY. An intervention would be evaluated as cost-effective if the threshold cost of the intervention was predicted positive. Overall, our results suggest

that screening-based vaccination could be cost-effective in six countries: Colombia, Brazil, Mexico, Malaysia, Thailand, and Puerto Rico, which have a GDP per capita ranging from $5,742 to $29,360. We have also found that screening-based vaccination would be cost-effective with a threshold cost ranging from $5 to $50 in the first five countries when the transmission intensity is high (SP9>0.5) with a highly sensitive and specific diagnostic; for Puerto Rico, the intervention could be cost-effective even when the transmission intensity is low (SP9≤ 0.3) and the threshold cost could reach $100 under stronger transmission.

POST-VACCINATION ANTIBODY RESPONSE OF DENGUE SEROTYPE 3 BREAKTHROUGH INFECTIONS

Cameron R. Adams, Ellen Young, Emily Gallichotte, Sandra Henein, Ralph Baric, Aravinda de Silva

University Of North Carolina, Chapel Hill, NC, United States

The four serotypes of Dengue virus (DENV1-4) are estimated to annually infect over 200 million people worldwide. In an effort to prevent DENV infection and disease, Sanofi Pasteur has developed a tetravalent live attenuated chimeric DENV vaccine (Dengvaxia) that aimed to elicit a protective response against DENV1-4. While Dengvaxia was deemed effective in two separate clinical trials in Asia and Latin America, vaccine efficacy varied depending on DENV serotype and pre-vaccination DENV immune status. Here we present analysis of vaccine elicited immune response of naïve and pre-immune subjects that experienced a DENV3 breakthrough infection. To understand the antibody response, we depleted specific populations of DENV-cross reactive antibodies from immune sera taken one month after final vaccination dose to estimate the contribution of serotype-cross reactive and type-specific antibodies to neutralization of DENV3. The majority of DENV naïve subjects who received the vaccine and then experienced a DENV3 breakthrough infection had no serotype specific response to DENV3 while developing other DENV serotype specific responses. For individuals who had neutralizing antibody response that was serotype-specific to DENV3 and still experienced a breakthrough infection, we mapped the DENV3 antibody response to specific epitopes using chimeric recombinant viruses. We discuss the implications of our results for understanding immune correlates and mechanisms of protective immunity against DENV3 following tetravalent DENV vaccination.

EMERGENCE OF A DENGUE VIRUS SEROTYPE 2 CAUSING A LARGE DENGUE EPIDEMIC IN SRI LANKA

Aruna Dharshan De Silva[1], Rashmi Tippalagama[1], Desha Dilani[1], Anishgoby Rajendran[2], Ranmalie Abeyesekere[1], Suraj Goonawardhana[1], Ananda Wijewickrama[3], Gayani Premawansa[4], Sunil Premawansa[5], Gathsaurie N. Malavige[6]

[1]Kotelawala Defence University, Ratmalana, Sri Lanka, [2]Genetech Research Institute, Colombo, Sri Lanka, [3]National Institute of Infectious Disease, Gothatuwa, Sri Lanka, [4]North Colombo Teaching Hospital, Ragama, Sri Lanka, [5]University of Colombo, Colombo, Sri Lanka, [6]University of Sri Jayawardenapura, Colombo, Sri Lanka

Severity of disease associated with dengue virus(DENV) infections in Sri Lanka has been increasing since 1989. It has been a reportable disease in Sri Lanka since 1996 and a severe epidemic occurred in 2009, involving the DENV1 serotype. Although many DENV serotypes, have been co-circulating in Sri Lanka, DENV1 was the predominant serotype from year 2008 to 2015, responsible for over 92% of infections, whereas DENV-2 and DENV-3 were not detected. There were 28,000 to 47,000 dengue cases per year reported between 2008 to 2015. Starting from mid-2016 there was a rapid increase in cases and the year 2017 had a total of 186,101 reported dengue cases with over 320 dengue related deaths. There was an increase in hospitalizations and severe disease. During our investigations it was discovered that a DENV2 strain was largely responsible for this outbreak and displaced the existing circulating DENV1. This study focuses on this dominant DENV2 strain, responsible for the 2016/2017 outbreak. For this study, the DENV2 strain was fully sequenced and phylogenetic trees (one using the full length and the second using the envelope region) were generated using the Neighbor joining method, based on Tamura-Nei model, with a bootstrap of 1000 replications. Phylogenetic analysis showed these DEN2 isolates belong to the cosmopolitan strains and are closely related to the 2015-2016 Singaporean strains. With daily frequent flights it is possible this strain spread from Singapore to Sri Lanka.

1618

MAGNITUDE AND FUNCTIONALITY OF NS1-SPECIFIC ANTIBODY RESPONSE ELICITED BY TAKEDA'S TETRAVALENT DENGUE VACCINE CANDIDATE

Dustin R. Glasner[1], Mayuri Sharma[2], Heather Watkins[2], Yoseph Kassa[2], Ralph Braun[2], Michael Egan[2], Hansi Dean[2], Eva Harris[1]

[1]Division of Infectious Diseases and Vaccinology, School of Public Health, University of California Berkeley, Berkeley, CA, United States, [2]Vaccines Business Unit, Takeda Pharmaceuticals Inc., Cambridge, MA, United States

Dengue virus (DENV) is the most medically important arbovirus, affecting 40% of people worldwide and infecting ~390 million individuals annually. Cases range from dengue fever to life-threatening dengue hemorrhagic fever/dengue shock syndrome, characterized by endothelial dysfunction and vascular leakage. Previously, we demonstrated that DENV nonstructural protein 1 (NS1) can induce endothelial hyperpermeability in both human cell culture and mouse models and that vaccination with NS1 confers antibody-mediated protective immunity. Takeda's live attenuated tetravalent dengue vaccine (TDV) candidate has structural proteins from each serotype on the DENV2 genomic backbone. Here, we evaluated the magnitude and functionality of the TDV NS1-specific antibody response. An indirect ELISA was used to measure DENV NS1-specific IgG in serum from 15 dengue-naïve and 15 pre-immune subjects, pre- (day 0) and 4 months post-vaccination (day 120). Naïve day 0 samples showed background IgG levels, whereas pre-immune day 0 and all post-vaccination samples displayed varying levels of IgG titers against DENV NS1. Vaccination with TDV increased DENV2 NS1-specific IgG levels in serum from all naïve and a few pre-immune subjects and was cross-reactive with NS1 from DENV1, 3, and 4. Using an *in vitro* model, we found that DENV2 NS1 induced endothelial hyperpermeability in human endothelial cell monolayers as measured by trans-endothelial electrical resistance, and hyperpermeability was not inhibited by pre-vaccination day 0 serum from naïve subjects. Pre-existing NS1-specific antibodies in day 0 serum from pre-immune subjects partially inhibited NS1-induced hyperpermeability. All post-TDV vaccination samples from both naïve and pre-immune vaccine recipients completely abrogated NS1-induced hyperpermeability. These effects correlated with anti-NS1 titers as measured by ELISA (r=0.6303, p=0.0089). Post-TDV vaccination serum also inhibited hyperpermeability induced by DENV1, 3, and 4 NS1 and reflected IgG titers. This is the first indication of functionality of NS1-specific antibody responses elicited by a candidate dengue vaccine.

CO-DEVELOPING CLIMATE SERVICES FOR PUBLIC HEALTH: STAKEHOLDER NEEDS AND PERCEPTIONS FOR THE PREVENTION AND CONTROL OF *AEDES*-TRANSMITTED DISEASES IN THE CARIBBEAN

Anna M. Stewart-Ibarra[1], Moory Romero[1], Mercy J. Borbor-Cordova[2], Shelly-Ann Cox[3], Avery Q. Hinds[4], Rachel Lowe[5], Roché Mahon[6], Cedric Van Meerbeeck[6], Leslie Rollock[7], Sylvester St. Ville[8], Sadie J. Ryan[9], Adrian Trotman[6]

[1]SUNY Upstate Medical University, Syracuse, NY, United States, [2]Escuela Superior Politécnica del Litoral, Guayaquil, Ecuador, [3]University of the West Indies, Bridgetown, Barbados, [4]Caribbean Public Health Agency, Federation Park, Trinidad and Tobago, [5]London School of Hygiene & Tropical Medicine, London, United Kingdom, [6]Caribbean Institute for

Meteorology and Hydrology, Bridgetown, Barbados, [7]Ministry of Health, St. Michael, Barbados, [8]Ministry of Health and Environment, Roseau, Dominica, [9]University of Florida, Gainesville, FL, United States

Diseases transmitted by *Aedes aegypti* (dengue, chikungunya, and Zika) are among the top public health concerns in the Caribbean. The 2017 Atlantic Hurricane Season was one of the most active on record; certain territories are now at greater risk of *Ae. aegypti* transmitted diseases due to damages to housing, infrastructure, and health systems, and increased mosquito larval habitats. Given the effects of local climate conditions (e.g., temperature and rainfall extremes) on the mosquito vector and disease transmission, the health and climate sectors have partnered to co-develop climate services to improve the management of these diseases, for example, through the development of climate-driven early warning systems. Here we present the results of a qualitative analysis of key stakeholder needs and perceptions in the region, with a focus on Barbados and Dominica. Stakeholders included public decision makers and practitioners from regional and national climate and health sectors. From April-June 2017, we conducted interviews (n=36), surveys (n=32), and national consultations with informants. Survey results were tabulated, and audio recordings were transcribed and analyzed by qualitative coding to identify themes. In surveys, 78% of health practitioners indicated that their jurisdiction is currently experiencing an increased risk of diseases transmitted by *Ae. aegypti* due to climate variability, and 81% of respondents anticipated that this risk will increase in the future. Interviewees identified strategies to strengthen the partnership between the climate and health sectors, and emphasized the need for local scientific evidence linking climate to health outcomes. Interviewees identified mechanisms for mainstreaming climate services for health operations to control *Ae. aegypti* transmitted diseases, such as an online GIS platform that would allow for data sharing and the generation of seasonal epidemic forecasts. These findings support the creation of transdisciplinary and intersectoral 'communities of practices' and the co-design of climate services for *Ae. aegypti* transmitted diseases in the Caribbean.

CLINICAL AND ANALYTICAL PERFORMANCE OF THE TRIOPLEX REAL TIME RT-PCR ASSAY DURING THE 2016 ZIKA EPIDEMIC IN PUERTO RICO

Gilberto A. Santiago, Jesus Vazquez, Jorge L. Munoz-Jordan

Centers for Disease Control and Prevention, San Juan, PR, United States

The emergence of Zika virus in 2015 presented a challenge to diagnostics in areas where transmission of dengue and chikungunya viruses has been detected. In response to this public health emergency, the Centers for Disease Control and Prevention developed the Trioplex Real Time RT-PCR Assay designed for the simultaneous detection of dengue, chikungunya and Zika virus RNA in human clinical specimen. We determined the analytical and clinical performance characteristics of the Trioplex in detecting each target virus serum, urine and whole blood-EDTA specimens. The assay was adapted to RNA extraction, PCR equipment and procedures commonly found in US and international public health laboratories. To determine the limit of detection (LoD) of the Trioplex for each target virus on each these modalities, inactivated dengue, chikungunya and Zika viruses were suspended in human serum, urine or whole blood and diluted to undetectable levels. The overall LoD for the assay was determined to approximate 10^3 genome copy equivalents per milliliter of specimen (GCE/mL) for every target virus. The assay modality that achieved the highest sensitivity included RNA extraction from 1 mL of specimen. Independent studies confirmed that the sensitivity of Trioplex is similar to other CDC and non-CDC tests; and that the Trioplex modality with the highest sensitivity compares favorably to the most sensitive commercial tests. In order to determine the clinical sensitivity of Trioplex during the first 6 days of illness, 373 concurrently collected serum, urine and whole blood samples from patients with positive Zika IgM after 7 days were tested. In 373 confirmed cases in Puerto Rico, the Trioplex detected 85% (317/373) in serum, 83% (311/373) in urine and 82% (285/347) in whole blood. Testing simultaneously collected serum and urine provides an additional 3% sensitivity over serum alone; whereas the value of testing serum-whole blood provides an additional 5% over serum alone. The high sensitivity of the Trioplex demonstrates the utility of the assay resolving Zika cases in endemic areas. More than 39 thousand Zika cases in Puerto Rico have been confirmed with the Trioplex.

1621

IMPROVEMENT OF THE DENGUE NON-HUMAN PRIMATE MODEL *VIA* A REVERSE TRANSLATIONAL APPROACH BASED ON DENGUE VACCINE CLINICAL EFFICACY DATA

Veronique Barban, Nathalie Mantel, Aymeric De Montfort, Anke Pagnon, Fabrine Pradezynski, Jean Lang, Florence Boudet

Sanofi Pasteur, Marcy L'Etoile, France

The non-human primate (NHP) model is the most widely recognized tool for assessing the protective activity of dengue vaccine candidates, based on the prevention of post-infection Dengue virus (DENV) viremia. However, the use of this model has been questioned after the recent Phase III trials with the tetravalent dengue vaccine (CYD-TDV) in which moderate protective efficacy against DENV-2 was reported, despite full protection against DENV-2 viremia previously being demonstrated in monkeys vaccinated with CYD-TDV. The aim of the present work was to re-assess the protection conferred by CYD-TDV in macaques, based on a reverse translational post-Phase III approach under more stringent conditions of DENV infection than previously employed. This strategy was based on the assumption that using viremia levels approximating those observed after natural dengue infection in humans, the new NHP model would have better ability than previously to predict the clinical efficacy of CYD-TDV against serotype 2. We show that the NHP model can be improved to achieve DENV-2 protection levels which show better agreement with clinical efficacy. We also demonstrate with this new model that injection of the CYD-2 component of the vaccine, either in a monovalent or a tetravalent formulation, is able to reduce DENV-2 viremia in all immunized animals. We also provide clear statistical evidence that DENV-2 neutralizing antibodies are able to reduce viremia in a dose-dependent manner. Collectively, these results reinforce the value of the NHP model in assessing the efficacy of dengue vaccines, despite inherent limitations.

IDENTIFICATION OF NOVEL TYPE-SPECIFIC NEUTRALIZING ANTIBODY EPITOPES IN THE DENGUE VIRUS TYPE 3 ENVELOPE GLYCOPROTEIN

Ellen Young[1], Daniela V. Andrade[2], Nurgun Kose[3], Magelda Montoya[2], Angel Balmaseda[4], Eva Harris[2], Jim Crowe[3], Ralph Baric[1]

[1]Department of Epidemiology, Chapel Hill, NC, United States, [2]Division of Infectious Diseases and Vaccinology, Berkeley, CA, United States, [3]Vanderbilt Vaccine Center, Nashville, TN, United States, [4]Laboratorio Nacional de Virología, Managua, Nicaragua

Four serotypes (1-4) of dengue virus (DENV) circulate in human populations, and immunity to one serotype does not confer long-lasting immunity to the others. Rather, pre-existing DENV immunity may actually increase the risk of severe dengue after exposure to a second serotype. The possibility of antibody-mediated enhancement has complicated vaccine development because of the need to induce robust immunity to all 4 serotypes simultaneously. After a primary infection, type-specific (TS) antibodies to the individual serotypes of DENV is thought to be associated with robust, life-long homotypic protection, but the full repertoire of primary neutralizing antibody epitopes in each DENV serotype remains incomplete. Currently, the only DENV3 TS neutralizing human monoclonal antibody (mAb) is 5J7, which recognizes a complex quaternary epitope that spans 3 monomers of the envelope (E) glycoprotein. Importantly, several studies have suggested that 5J7 may not be the only neutralization epitope in DENV3. Rather, studies in natural DENV-infected cohorts and in vaccinees receiving tetravalent DENV vaccine suggest only a fraction of

the polyclonal response targets the 5J7 epitope and there are additional neutralizing epitopes. To test this hypothesis, we immortalized memory B cells from DENV3infected individuals from a cohort in Nicaragua. Several additional DENV3 TS neutralizing mAbs were identified that do not compete with 5J7 in competition assays. One mAb, 66, neutralizes genotype III but not genotype II variants of DENV3. A second neutralizing human mAb, 144, binds to E domain 1 (EDI) as determined by lack of neutralization of chimeric viruses. A third DENV3- specific neutralizing human mAb, 115, binds to a novel epitope located outside the EDI/II hinge and EDI regions. Refined epitope mapping and epitope exchange studies are in progress to definitively map the epitopes of these new DENV3 neutralizing mAbs. These findings provide new insights into the mechanism of DENV3 neutralization and will lead to assays for defining the primary neutralizing epitopes associated with DENV3 protective immunity following natural infection or vaccination.

1623

POTENCY AND BREADTH OF HUMAN IMMUNE SERA FOLLOWING PRIMARY DENGUE VIRUS INFECTION

Chad D. Nix, Bettie W. Kareko, Brian L. Booty, Jules B. Weinstein, Zoe L. Lyski, William B. Messer

Oregon Health & Sciences University, Portland, OR, United States

Characterization of the antibody response following infection with one of the four dengue virus (DENV1-4) serotypes is often incompletely defined, in part because of antigenic diversity between DENV within each serotype. Historically DENV immune sera are characterized using either locally circulating or reference DENV isolates, often with only one virus per serotype. However, the DENV field has increasingly recognized the potential for within serotype antigenic variation to contribute to breakthrough infection following DENV vaccination and, potentially, natural DENV infection. Consequently, approaches to characterize immune sera that capture and compare the interplay between antigenic diversity and antibody neutralization are called for. The objective of this study is to characterize and compare the potency and breadth of neutralization of 1° DENV immune sera by applying approaches developed in the HIV field to characterize breadth and potency of HIV neutralizing antibodies. In this context, breadth refers to the overall antigenic diversity contained within a panel of unique viruses and potency refers to the each serum neutralization titer (NT) against each unique virus. To execute this study, immune sera from individuals with diverse geographic (South and Central America, South Asia, Southeast Asia and Oceana) and temporal (0.7 to 36 years prior) 1° DENV1 infection histories were characterized against a panel of 10 genetically distinct DENV1 virus isolates. For each serum and virus set, proportion of viruses neutralized are plotted against serum dilution, generating a unique curve for each serum that characterized the potency and breadth of serum neutralization. We then describe and compare the curves using both traditional and novel statistical methods, providing a robust means of comparing individual serum neutralization properties in a manner that captures the full activity of each serum against a diverse panel of virus isolates. This approach is generalizable to all four DENV serotypes and should provide a more rigorous approach to characterizing DENV immune sera following both vaccination and natural infection.

1624

SEROLOGICAL DISCRIMINATION OF DENGUE AND ZIKA INFECTIONS

Freddy A. Medina, Frances Vila, Jorge L. Muñoz-Jordán

Centers for Disease Control, San Juan, PR, United States

The arrival of Zika virus (ZIKV) to dengue DENV endemic areas came along with diagnostic challenges in serology. The current ELISA assays cannot distinguish these viruses. Furthermore, cross-reactive antibodies produced in DENV and ZIKV infections make the PRNT unreliable for diagnostic purposes as most dengue endemic countries experienced ZIKV mainly as a secondary flavivirus infection. The goal of this study was to develop a MAC-ELISA that could simultaneously discriminate between DENV and ZIKV infections during the convalescent phase during which molecular diagnosis is no longer reliable. A ZIKV/DENV MAC-ELISA was developed to detect the presence of ZIKV or DENV IgM simultaneously. We analyzed PCR-confirmed acute and convalescent cases of ZIKV, DENV, and non-flavivirus febrile illness from our established Sentinel Enhanced Dengue Surveillance System (SEDSS) in Ponce, Puerto Rico. Infections were identified with a diagnostic algorithm that utilized the ratio of the average OD450 reacting to ZIKV antigen/average OD450 reacting to DENV antigen to determine ZIKV positive cases. This was followed by calculating the average OD450 to DENV/the average OD450 to the normal antigen to determine DENV positive cases. Specimens that did not react above the cutoff value for DENV were considered negative for both viruses. The ZIKV/DENV duo MAC-ELISA was able to detect 103/103 (100%) ZIKV+ specimens and discriminated 103/103 (100%) of the specimens correctly. For DENV+ specimens, the ZIKV/DENV duo MAC-ELISA detected 133/134 (99.25%) and correctly discriminated 133/133 (100%). The sole specimen not detected or discriminated was equivocal in the assay. No false positives were detected from 143 negative specimens tested. A novel approach to differentiate DENV and ZIKV infections serologically was developed. Our ZIKV/DENV duo MAC-ELISA displayed sensitivity that was equivalent to both ZIKV and DENV stand-alone assays. The assay specificity was high enough that it can potentially replace the highly laborious PRNT for confirmation of ZIKV or DENV IgM detection.

1625

CHARACTERIZATION OF A MURINE MODEL OF NON-LETHAL, SYMPTOMATIC DENGUE VIRUS INFECTION

Vanessa V. Sarathy, Mellodee White, Li Li, Jaclyn A. Kaiser, Gerald A. Campbell, Gregg N. Milligan, Nigel Bourne, Alan D. Barrett

Univ of Texas Medical Branch, Galveston, TX, United States

The mosquito-borne disease dengue is caused by four serologically- and genetically- related viruses, termed DENV-1 to DENV-4. Clinical dengue infections range in severity from self-limiting, debilitating disease to life-threatening illness, such as dengue hemorrhagic fever and dengue shock syndrome. A major obstacle in dengue research had been the lack of appropriate animal models that mimic human disease. Recent advances using the immunocompromised AG129 mice (deficient in IFN-α/β/γ receptors) resulted in development of lethal murine infection models for DENV-1-4 that reproduce key features of severe dengue. In this study, we compared a non-lethal, disseminated model of DENV-3 infection using strain D83-144 to that of the lethal outcome following infection by strain DENV-3 C0360/94. Intraperitoneal inoculation of AG129 mice with strain D83-144 led to a neutralizing antibody response and to clinical signs of dengue infection, such as serum cytokine induction, thrombocytopenia, leukopenia, organ pathology, and disseminated viral loads. However, C0360/94 infection led to increased clinical disease and to additional features of severe human dengue, such as coagulopathy and lethal outcome. Genome sequencing revealed that both DENV-3 strains belong to the same phylogenetic group, genotype II, and differ by only 13 amino acids. The results suggest that the AG129 mouse model has applications to investigate differences between mild and severe disease. This study is the first to investigate a low passage, non-mouse lethal strain in AG129 mice that causes a productive, mild infection with features of human dengue.

1626

ENDEMICITY AND EMERGENCE OF ARBOVIRUSES IN PIEDECUESTA, COLOMBIA

Maria Isabel Estupiñán Cardenas[1], Isabel Rodriguez-Barraquer[2], Rosa Margarita Gélvez[1], Anyela Lozano[1], Victor Mauricio Herrer[1], Jessica Vanhomwegen[3], Henrik Salje[3], Jean-Claude Manuguerra[3], Derek A. Cummings[4], Maria Consuelo Miranda[1], Luis Angel Villar Centeno[1]

[1]Universidad Industrial de Santander, Bucaramanga, Colombia, [2]University of California San Francisco, San Francisco, CA, United States, [3]Institut Pasteur, Paris, France, [4]University of Florida, Gainesville, FL, United States

For diseases like dengue (DENV) or Zika (ZIKV), where a large proportion of infections are asymptomatic, population-based serological studies remain the gold-standard to quantify transmission. Here, we present preliminary findings from our population based studies conducted in Piedecuesta, Colombia since 2014. These studies include a baseline household-based cross-sectional sero-survey conducted among 1200 individuals in 2014, as well as an ongoing longitudinal cohort that enrolled 2400 participants in 2015. Follow-up within the cohort study involves active fever surveillance (via a call center) as well as yearly visits in which a blood sample is collected. While these studies were originally designed to characterize dengue transmission, chikungunya (CHIKV) and ZIKV were introduced into the study area in 2014 and 2016, respectively. Thus, they provide a unique opportunity to quantify transmission of the three viruses and identify risk factors for infection and disease. At baseline, 67% (1636/2453) of participants tested positive for IgG against DENV and the age-specific seroprevalence pattern was consistent with endemic circulation of DENV in this population. Up to now, during over 5000 person-years of follow-up, there have been 813 incident cases of febrile illness, including 14 cases of DENV, 14 cases of CHIKV and 73 cases of ZIKV confirmed by PCR and/or serology. We are currently testing the samples from the yearly visits to ascertain seroconversion. Serological testing is being performed using a multiplex recombinant antigen-based microsphere immunoassay that simultaneously quantifies IgG against multiple arboviruses. This assay was validated using over 400 well characterized samples from the cohort study and shown to have good sensitivity and specificity for CHIKV, DENV and ZIKV. Once testing is complete, we will estimate the attack rates of the three viruses, the symptomatic to asymptomatic ratios, and risk factors associated with infection and disease. In particular, we will explore whether prior exposure to DENV modified the risk and/or outcome of ZIKV infection during the 2016 outbreak.

1627

AVIAN IGY ANTIBODIES RECOGNIZE NOVEL DENGUE NS1 EPITOPES WITH THE ABILITY TO NEUTRALIZE INFECTION AND REDUCE VASCULAR LEAKAGE WITHOUT INDUCING ANTIBODY DEPENDENT ENHANCEMENT

Kyle L. O'Donnell[1], Diego Espinosa[2], Matthew L. Nilles[1], Eva Harris[2], David S. Bradley[1]

[1]University of North Dakota, Grand Forks, ND, United States, [2]University of California Berkeley, Berkeley, CA, United States

Dengue virus (DENV), the most prevalent arbovirus, causes 96 million infections worldwide resulting in 500,000 cases of Dengue Hemorrhagic Fever (DHF) cases and 22,000 deaths. Symptoms of DENV infection range from a mild fever to extensive vasculature permeability resulting in hemorrhagic fever, shock, and death. The severity of DENV infection is greatly enhanced by antibody dependent enhancement (ADE); increased viral load due to increased monocyte opsonization by non-neutralizing low avidity Abs from a different DENV serotype or secondary flavivirus infection. ADE has made both passive and active vaccines difficult to develop. We have previously demonstrated that polyclonal avian anti-DENV-2 IgY ameliorates DENV infection in mice without inducing ADE. We had hypothesized that IgY would not induce ADE as mammalian Fc receptors are unable to bind the Fc portion of IgY, and thus IgY would have the potential to provide a viable treatment for DENV infections. Epitope-mapping of anti-DENV-IgY identified numerous epitopes of the envelope, membrane, and non-structural (NS) proteins that were recognized. Here we demonstrate that two purified pools of anti-DENV IgY with specificity for two different regions of NS1 had a neutralization capacity equivalent to the whole polyclonal DENV IgY preparation *in vitro*. We assayed each pool of NS1-specific IgY for the potential to induce ADE and demonstrated no ADE when cells were treated with IgY and challenged with a secondary flavivirus. We then utilized a trans-endothelial electrical resistance (TEER) assay and determined that treatment with DENV NS1-specific IgY reduced vascular leakage in our model system. We propose IgY may provide a novel oligoclonal therapeutic for human DENV infection without inducing ADE.

1628

TOWARDS THE DEVELOPMENT OF A FEASIBLE DENGUE FORECASTING SYSTEM IN AN ENDEMIC COUNTRY

Katia Charland[1], Elaine Nsoesie[2], Mabel Carabali[3], Gloria Jaramillo Ramirez[4], Cesar Balaguera[4], Mathieu Maheu-Giroux[3], Audrey Smargiassi[1], Moritz UG Kraemer[5], Erin Rees[6], Linda Vrbova[7], Alexandra Schmidt[3], **Kate Zinszer**[1]

[1]University of Montreal, Montreal, QC, Canada, [2]University of Washington, Seattle, WA, United States, [3]McGill University, Montreal, QC, Canada, [4]Universidad Cooperativa de Colombia, Neiva, Colombia, [5]Harvard Medical School, Boston, MA, United States, [6]Public Health Agency of Canada, St-Hyacinthe, QC, Canada, [7]Public Health Agency of Canada, Guelph, ON, Canada

Disease forecasting systems vary in complexity and are largely based on the analysis of routine data such as disease surveillance, socio-economic, meteorological, and land use data. In countries with limited resources, a user-friendly forecasting system based on strategically chosen input data sources may be necessary. The objective of this research was to develop and validate such a forecasting model for short-term (1 and 2 month-ahead) and long-term (year-ahead) predictions of dengue incidence based on monthly municipality-level data for Colombia from 2014 to 2016. We used a machine learning approach and specifically, a random forest algorithm, as it is known to have good prediction accuracy in a variety of contexts and can rank predictors/inputs in terms of their relative importance to prediction. We considered the following inputs: socio-economic, meteorological, land cover, and historical arbovirus disease surveillance notifications (i.e., cases of Zika, chikungunya, dengue). In our preliminary results of year-ahead forecasts of dengue incidence in 2016, based on 2014-15 predictors, the best model included land cover, SES, and historical arbovirus disease notifications with a good prediction accuracy ($R^2 = 0.66$). Historical dengue incidence was the strongest predictor followed by evergreen/deciduous needleleaf tree landcover and the average household index of unsatisfied basic needs. However, a simpler model using only historical chikungunya and dengue incidence provided forecasts with similar prediction accuracy. In short-term forecasts, the 1 month-ahead model with predictors, historical dengue and chikungunya, and rainfall had high prediction accuracy ($R^2 = 0.89$). The best 2 month-ahead model, allowing 1 month lead time, had the same predictors but had lower accuracy ($R^2=0.70$). Our next steps include exploring higher temporal resolution forecasts (e.g., weekly) at lower spatial resolutions (e.g., department level) for 2017. Our preliminary work suggests that investment in disease surveillance data may be more efficient than investing in the processing and management of climate/meteorological variables.

1629

VALIDATION OF CLINICAL ALGORITHMS FOR THE DIAGNOSIS OF DENGUE IN ENDEMIC AREAS OF COLOMBIA

Diana M. Caicedo, José R. Tovar, Lyda Osorio

University of Valle, Cali, Colombia

Due to the increase mortality of dengue, its prompt and correct diagnosis is a priority for clinical care in endemic countries. Clinical classifications and existing laboratory tests for diagnosis have a variable performance in terms of sensitivity and specificity. To develop and validate clinical algorithms for dengue diagnosis in endemic areas of Colombia. A Bayesian-adaptive quasi-experimental clinical trial has been conducted with a target of 2000 febrile subjects. In the first phase, diagnostic algorithms based on Bayesian methodologies are been developed and validated prospectively. Demographics, signs and symptoms of dengue, leukocytes and platelets are collected from all participants; clinical algorithms are compared to gold standard diagnostic dengue tests (combination of NS1-ELISA, IgM/IgG-ELISA, RT-PCR). In the second phase, the diagnostic accuracy of the best algorithm identified in the first phase will be validated in the routine clinical practice. Interim analyses will be performed when effective sample size is met. Bayesian estimates of sensitivity and specificity were made. To date, 8 clinical diagnostic algorithms have been developed. Four based on signs and symptoms and four that include leukocytes and platelet counts. The latter have reached up to 81,3% sensitivity and 88,2% specificity. In addition, in a prospective validation 536 febrile subjects were recruited and the clinical algorithm (headache, skin rash, hemorrhagic manifestations, warning signs, neurological alterations, absence of respiratory symptoms, leukopenia <4.200/mm³ and thrombocytopenia <165.000/mm³) had a sensitivity of 70,5% and a specificity of 65%. The inclusion of blood count parameters using Bayesian methods improves the sensitivity of dengue diagnostic algorithms based only on signs and symptoms. The development of highly sensitive and specific dengue diagnostic tests based on clinical criteria useful at point of care remains a challenge for dengue research.

DIMER-DEPENDENT QUATERNARY EPITOPES ENHANCE QUALITATIVE IMMUNE RESPONSES IN FLAVIVIRUS E-SUBUNIT VACCINE CANDIDATES

Stefan W. Metz, Ashlie Thomas, Xianwen Yi, Jason Coffman, Jillian Perry, Michael J. Miley, Shaomin Tian, Aravinda M. de Silva

University of North Carolina at Chapel Hill, Chapel Hill, NC, United States

Flaviviruses are a group of arthropod-borne viruses that represent a major public-health threat all over the globe. Several hundred million people are infected by DENVs, of which many develop dengue fever or dengue hemorrhagic fever. The same populations are at risk to other closely related flaviviruses. Since early 2015, Zika virus (ZIKV) has spread from Brazil to most countries in Latin America, the Caribbean, and most recently, the USA. ZIKV infection can lead to neurological disorders and has been linked to severe birth defects. There is an urgent need for vaccines to protect individuals and to prevent the spread of these viruses. Results from flavivirus vaccine trials establish the importance of the "quality" of a neutralizing response for developing durable protective immunity. Neutralizing Ab quality refers to the capacity to recognize serotype-specific targets of complex structure on the surface of the virion. Recent studies have established that quaternary epitopes and larger antigenic sites displayed on flavivirus E protein homodimers, but not monomers, are major targets of type-specific and cross-protective neutralizing Abs. To explore the potential of E-protein based subunit vaccines, we have immobilized soluble E molecules on solid carriers, and induced the formation of stable homodimers These *in vitro* assembled homodimers were efficiently recognized by human Abs directed to quaternary structure epitopes. Most importantly, mice immunized with immobilized DENV2 and ZIKV rE-homodimers developed more rapid and higher neutralizing Ab responses compared to animals immunized with monomers. Our data indicates that targeting quaternary epitopes present on E-homodimers that are displayed on particles induced a higher quality immune response compared to E-monomers, therefore enhancing the quality of the immune responses. These findings represent promising tools to develop safe and efficacious flavivirus vaccine candidates.

Dengue viruses (DENVs) place over 2 billion people at risk of infection each year rendering them the most aggressive Arboviruses worldwide. There are four serotypes of DENVs. Infection with one serotype does not cross protect from infection with other serotypes. No treatment options exist due to complications in disease pathology mediated by the immune response. Using state of the art high resolution metabolomics analyses of serum derived from pediatric patients we have identified metabolite biosignatures that are strongly associated with dengue disease severity and pathogenesis. These metabolite biosignatures also very clearly distinguish the pathogenic states caused by Zika virus and chikungunya infections with a combined accuracy of 99-100%. Thus, they have a strong potential to play a critical role in better triaging and clinically managing these viral diseases at an early stage. Additionally, unbiased network and pathway analyses identified fatty acid metabolism as a critical pathway that differentiated the disease states associating observations made at a molecular level with those in humans. Given that lipids play an active role in immune cell development, maturation and immune-mediated pathology these metabolic changes may be critical for establishing productive infections primarily via detrimental effects on the immune response.

FIRST ISOLATION OF DENGUE VIRUS SEROTYPE 3 IN A NORTH REGION OF PERU: MOLECULAR DIAGNOSIS AND CLINICAL CHARACTERISTICS

Miguel A. Aguilar-Luis[1], Johanna Martins-Luna[2], Wilmer Silva-Caso[3], Claudia Weilg[2], Fernando Mazulis[2], Luis del Valle[4], Fernando Vásquez-Achaya[2], Jorge Bazán-Mayra[5], Víctor Zavaleta[5], Homero Bazán-Zurita[6], Juana del Valle-Mendoza[3]

[1]Universidad Peruana de Ciencias Aplicadas, Instituto de Investigación Nutricional, Instituto de Investigación de Enfermedades Infecciosas, Lima, Peru, [2]Universidad Peruana de Ciencias Aplicadas, Lima, Peru, [3]Universidad Peruana de Ciencias Aplicadas, Instituto de Investigación Nutricional, Lima, Peru, [4]Universidad Politécnica de Catalunya, Lima, Spain, [5]Dirección Regional de Salud de Cajamarca, Lima, Peru, [6]Universidad Privada Antonio Guillermo Urrelo, Lima, Peru

Dengue virus (DENV) infection is the most rapidly spreading mosquito-borne viral disease. DENV-1 and DENV-2 have been associated with severe cases of DENV infection such as dengue hemorrhagic fever (DHF) and dengue shock syndrome (DSS). DENV-2 is the most commonly isolated serotype in Perú and DENV-3 has only been previously described once in Peru. This study aimed to describe an outbreak of DENV infection in Cajamarca during 2017 and to molecularly identify the involved serotypes. A total of 359 serum samples from patients with acute febrile illness (AFI)

were assessed for the presence of dengue virus via RT-PCR, ELISA NS1, IgM and IgG. DENV positive samples were classified by serotypes 1 to 4 depending on their amplified primers. Dengue virus was detected in 24,7% (n=89) of samples via RT-PCR. Serological analysis detected 35.7% (n=128) positive cases via ELISA NS1 antigen, 16.7% (n=60) via ELISA IgG and 9.7% (n=35) via ELISA IgM. DENV-2 serotype was isolated in 11.2% (n=10) and DENV-3 serotype in 77.5% (n=69). We could not identify the serotype of 11.2% (n=10) of DENV cases confirmed by RT-PCR. The most frequent symptoms found in patients positive for DENV (RT-PCR) overall were, headaches (88.8%), followed by arthralgias (71.9%) and myalgias (68.5%). DENV-3 infected patients reported headache (88.4%) followed by myalgias (73.9%) and arthralgias (66.7%), as their most common symptoms. No DHF, DSS or deaths were reported during this outbreak. In conclusion, in our study, we identified DENV in 24,7% of samples during a dengue outbreak in Cajamarca. The serotype characterization showed that 77,5% DENV infection cases were caused by DENV-3, which represents the first isolation of this serotype in Cajamarca and the second time DENV-3 is described in Peru. These findings demonstrate an increasing extension of serotype 3 in Peru and highlights the importance of molecular diagnosis and serotype characterization among the clinically-defined dengue cases to strengthen the Peruvian epidemiological surveillance and decrease under-reporting rates in the Americas.

1633

ANTIBODY PERSISTENCE AND IMMUNE MEMORY RESPONSE FOLLOWING VACCINATION WITH LIVE ATTENUATED SA 14-14-2 JAPANESE ENCEPHALITIS VACCINE [CD.JEVAX, CHENGDU INSTITUTE OF BIOLOGICAL PRODUCTS]

K. Zaman[1], Md. Yunus[1], **Jodi Feser**[2], Asma B. Aziz[1], Jessica Mooney[2], Yuxiao Tang[2], Damon W. Ellison[3], Lei Zhang[4], G. William Letson[2], Anthony A. Marfin[2]

[1]International Centre for Diarrhoeal Disease Research, Bangladesh, Dhaka, Bangladesh, [2]PATH, Seattle, WA, United States, [3]Armed Forces Research Institute of Medical Sciences, Bangkok, Thailand, [4]Chengdu Institute of Biological Products, Chengdu, China

Japanese encephalitis (JE) virus is the leading cause of viral encephalitis across temperate and tropical zones of Asia. The live attenuated SA 14-14-2 JE vaccine (CD-JEV) is one of several vaccines prequalified by the World Health Organization to prevent JE. Previous trials with CD-JEV have shown that more than 90% of vaccinees developed neutralizing antibody (nAb) titer at seroprotective levels of ≥1:10 one month after vaccination, and in two studies, more than 80% of participants maintained nAb titers ≥1:10 up to four years after vaccination. This Phase 4 open-label clinical study evaluated nAb titers in Bangladeshi children three and four years after primary CD-JEV vaccination in a previous study and 7 and 28 days following receipt of a CD-JEV booster dose in this study. Three years after initial vaccination, seroprotective nAb titers of ≥1:10 were measured in 328 of 561 children (58.5% [95% CI: 54.3-62.5]) using the plaque reduction neutralization test. No vaccine-associated neurologic adverse events or other serious adverse events or safety signals were noted in children who were given a booster CD-JEV dose. Neutralizing antibody titer results four years after primary vaccination and 7 and 28 days following the CD-JEV booster dose are expected in August 2018.

ZIKA VIRUS FORECASTING AND PREDICTION STUDIES: A SYSTEMATIC REVIEW AND EVALUATION OF THEIR UTILITY DURING A GLOBAL HEALTH EMERGENCY

Pei-Ying Kobres[1], Jean-Paul Chretien[2], Cecile Viboud[3], Matthew Biggerstaff[4], Talia Quandelacy[5], Pai-Yei Whung[6], Jeffrey Morgan[7], Michael Johansson[4], Simon Pollett[8]

[1]George Washington University, Washington, DC, United States, [2]Department of Defense, Frederick, MD, United States, [3]National Institutes of Health, Bethesda, MD, United States, [4]Centers for Disease Control and Prevention, Atlanta, GA, United States, [5]Johns Hopkins University, Baltimore, MD, United States, [6]Environmental Protection Agency, Washington, DC, United States, [7]Joint Research and Development, Inc, Stafford, VA, United States, [8]Walter Reed Army Institute of Research, Silver Spring, MD, United States

Numerous quantitative predictions were published during the 2016-2017 Zika virus (ZIKV) pandemic yet it remains unknown how timely, reproducible and actionable they were. We therefore conducted a systematic review and evaluation of all ZIKV prediction studies published during the recent ZIKV pandemic. We adapted the PRISMA methodology. All studies which forecasted, predicted or simulated any ecological or epidemiological phenomenon about the Zika pandemic and published prior to March 01 2017 were identified via MEDLINE, EMBASE and grey literature review. Eligible studies underwent evaluation of methods, data sources, objectives, timeliness, reproducibility, accessibility and clarity. 2034 studies were identified, of which 73 met eligibility criteria. The majority of studies predicted spatial spread, Ro or epidemic dynamics. Few studies predicted Guillain-Barre Syndrome burden (4%), sexual transmission risk (4%) and intervention impact (4%). Most studies specifically examined populations in the Americas (52%), with very few African-specific studies (4%). Case count, vector and demographic data were the most common data sources. Few studies used real-time internet data (7%) and none used genomic data. Deterministic models were more commonly used. 22% of studies did not make any model data available, 62% did not provide model code, 39% did not present uncertainty in predictions and 46% did not provide complete methodological detail. 59% of predictions were published after the epidemic peak in the Americas. Pre-prints improved the accessibility of ZIKV predictions (median 132 days sooner than journal publication date), but were used in only 32% of studies. In conclusion, many ZIKV predictions were published during the 2016-2017 pandemic. The accessibility, reproducibility, timeliness and incorporation of uncertainty in these published predictions varied. Improvements in the sharing of model data and code, methodological reporting and use of pre-prints can improve future outbreak responses.

1635

EFFECT OF TEMPERATURE ON THE EXTRINSIC INCUBATION PERIOD OF ZIKA VIRUS IN *AEDES AEGYPTI*

Olivia C. Winokur, Bradley J. Main, Jay Nicholson, Christopher M. Barker

University of California Davis, Davis, CA, United States

Since Zika virus (ZIKV) emerged as a global human health threat, numerous studies have pointed to *Aedes aegypti* as the primary vector due to its high competence and propensity to feed on humans. However, all published vector competence studies have been conducted between 26°C-28°C, and arboviral extrinsic incubation periods (EIPs), and therefore transmission efficiency, are known to be strongly affected by temperature. To better understand the relationship between ZIKV EIPs and temperature, we evaluated the effect of adult mosquito exposure temperature on ZIKV infection, dissemination, and transmission in *Ae. aegypti* at four temperatures: 18°C, 22°C, 26°C, and 30°C. Mosquitoes fed on mice infected with a 2015 Puerto Rican ZIKV strain and were sorted into the four temperatures with 80% RH and constant access to 10% sucrose. ZIKV infection, dissemination, and transmission rates were estimated via RT-qPCR from individual mosquito bodies, legs and wings, and saliva, respectively, at 3-5 time points per temperature from 3 to 31 days, based on data from other flavivirus EIPs. Twenty mosquitoes were tested at each time point. Of the 320 mosquitoes that fed and survived the duration of the study, 312 (97.5%) were infected with ZIKV, 264 (82.5%) disseminated, and 144 (45%) transmitted at the time point tested. The median time from ZIKV ingestion to transmission (median EIP, EIP50) at each temperature was estimated by fitting a generalized linear mixed model. EIP50 ranged from 5.1 days at 30°C to 25.0 days at 22°C. At 26°C, EIP50 was 9.4 days. At 18°C, only 15% transmitted by day 31 so EIP50 could not be projected. This is the first study to characterize the effects of temperature on ZIKV EIP in *Ae. aegypti*. These results deviate slightly

from EIPs of dengue virus in *Ae. aegypti* and West Nile virus in *Cx. tarsalis.* This information is critical for modeling ZIKV transmission dynamics to understand geographic and seasonal limits of ZIKV risk; it is especially relevant for determining risk in subtropical regions with established *Ae. aegypti* populations (e.g. California or Florida) as these regions typically experience cooler temperature ranges than tropical regions.

1636

CONTRASTING THE VALUE OF TARGETED VERSUS AREA-WIDE MOSQUITO CONTROL SCENARIOS TO LIMIT ZIKA VIRUS TRANSMISSION FOR DIFFERENT TROPICAL URBAN POPULATION CENTERS

Chris Stone[1], Samantha Schwab[2], Dina Fonseca[2], Nina Fefferman[3]

[1]University of Illinois at Urbana-Champaign, Champaign, IL, United States, [2]Rutgers University, New Brunswick, NJ, United States, [3]University of Tennessee, Knoxville, TN, United States

Transmission of vector-borne diseases is affected by various types of host movement. Here we consider the extent to which considering daily commuting patterns can help optimize vector control efforts to limit the size of Zika virus outbreaks. We examine three tropical urban centers (San Juan, Recife, and Jakarta) that have been exposed to Zika and/or dengue outbreaks in recent years and consider whether the distribution of human populations and resulting commuting flows has an impact on the optimal scale at which to implement control interventions. We developed a stochastic, spatial model adapted to these three urban areas and four control scenarios based on larval control. The scenarios differed in the spatial extent of their implementation and were: 1) a response at the level of an individual neighborhood; 2) a response targeted at a neighborhood with active transmission and one with which it was most strongly connected; 3) a limited area-wide response where all neighborhoods within a certain radius of the focal area were included; and 4) a collective response where all participating neighborhoods implemented control. The relative effectiveness of the scenarios varied only slightly between different settings, with the number of infected cases averted over the course of the epidemic increasing with the scale of implementation. This difference depended strongly on the efficacy of control at the neighborhood level. At low levels of efficacy, the scenarios mirrored each other in cases averted. At high levels of efficacy, impact increased with the scale of the intervention. This occurs because at high levels of efficacy, more focal responses lead to stronger metapopulation dynamics after the epidemic peak. Despite this, more focal responses still require a lower population coverage, and the choice between scenarios will largely be a function of the amount of effort decision-makers are willing to invest. Finally, we consider how the spatial configuration of control can improve the efficacy of control programs, pointing to ways in which improved knowledge of vector densities and human movement can optimize control efforts.

1637

THE EFFECT OF TIMELY INTENSIVE SPACE SPRAY ON DISEASE CONTROL IN TWO ZIKA VIRUS OUTBREAKS IN SOUTHERN THAILAND

Theerut Densathaporn[1], Somchai Nakthungtao[2], Virasakdi Chongsuvivatwong[1], Rassamee Sangthong[1], Mekkla Thompson[3]

[1]Epidemiology Unit, Faculty of Medicine, Prince of Songkla University, Hat Yai, Songklha, Thailand, [2]Ban Na San District Health Office, Ban Na San, Suratthani, Thailand, [3]Westat, Rockville, MD, United States

Main Zika virus (ZIKV) transmission is via mosquito vectors. Theoretically, rapid viremia occurs after onset in human case and short intrinsic incubation period in vector mosquito indicate the needs to lauch an intensive space spray within 3 days of onset of each case in order to prevent ZIKV transmission. However, whether this timeliness could be reached and whether it can actually stop the outbreak have never been epidemiologically examined. This study aimed to investigate the proportion of timely intervention and check whether it could reduce secondary infection rate. Data on two ZIKV outbreaks in 2015-2016 from two communities, A and B, were analyzed. Main variables included disease onset, house coordinates and date of spray around the cases' house. ZIKV was confirmed by RT-PCR. Potential secondary cases were patients with onset at 3 to 23 days after the index cases and lived nearest to them in the same community. Timely spray was achieved in 5 of 18 and 9 of 15 cases' households in Community A and B, respectively. In Community A, the mean (SD) of secondary case infection rates were 0.92 (1.12) and 0.20 (0.45) in the non-timely and timely groups, respectively. Consistent pattern was observed in Community B where mean (SD) of secondary case infection rate were 1.67 (1.63) and 0.33 (0.43) in the non-timely and timely groups, respectively. The timely spray could reduce secondary cases by (.92-.2)/.92 = 78.3% in Community A and (1.67-.33)/1.67 = 80.2% in Community B. Combining data from these two communities, rate of secondary infections in the timely group was significantly fewer than that in the non-timely group (ranksum test P value = 0.029). Thus, the timely space spray could reduce secondary case infection rate. However, delayed spray was still preponderant. Researches to increase timeliness for intensive spray are needed to improve future ZIKV outbreak control.

1638

ARBOVIRAL DISEASE IN PAKISTAN: 2015-2017

Kelli L. Barr[1], Erum Khan[2], Dhani Prakoso[1], Joveria Farooqi[2], Faisal Malik[2], Kehkashan Imtiaz[2], Maureen T. Long[1]

[1]University of Florida, Gainesville, FL, United States, [2]Aga Khan University, Karachi, Pakistan

Like most of the world, Pakistan has seen an increase in mosquito-transmitted diseases in recent years. The magnitude and distribution of these diseases are poorly understood as Pakistan does not have a nation-wide system for reporting disease. A cross-sectional study to determine which arboviruses were the cause of disease in Pakistan was instituted. Over the course of 2 years, 997 patients were enrolled presenting with clinical features suggestive of arboviral disease. Viral exposure was verified via detection of viral nucleic acids or virus-specific IgM with virus-specific neutralizing antibodies. In addition, clinical and pathological data were collected. It is not uncommon for Dengue viruses (DENV) to co-circulate West Nile virus (WNV), Japanese Encephalitis virus (JEV), and/or Chikungunya virus (CHIKV) which can lead to misdiagnosis. Overlapping clinical presentation and serological cross-reactivity complicate definitive diagnosis. Furthermore, secondary infections with these types of viruses can exacerbate clinical symptoms and complicate interpretation of diagnostic tests. Here we describe the active and persistent circulation of WNV, DENV, JEV, and CHIKV in Pakistan. We found that these viruses exhibited unique characteristics that could help local practitioners drive surveillance, diagnostics, and improve patient care. WNV infection occurred primarily in the early spring and fall months with many patients presenting with altered mental status (OR 4.25, CI 1.32-13.69) or seizures (OR 2.58, CI 0.66-10.14). Individuals with JEV infection were more likely to have gastro-intestinal disturbances (OR 7.16, CI 1.54-33.21) and a complete lack of neurological manifestations (OR 0.13, CI 0.03-0.62). We found that CHIKV has been circulating in Pakistan since at least 2015 and is a significant cause of neuroinvasive disease in nearly half of exposed patients (OR 3.5, CI 0.93-13.19). Moreover, the majority of CHIKV infections occurred in the winter months when *Aedes* mosquitos are typically dormant. DENV infections occurred primarily in the early summer months and all 4 serotypes co-circulated and co-infected patients.

1639

IDENTIFYING ENVIRONMENTAL RISK FACTORS AND MAPPING THE RISK OF HUMAN WEST NILE VIRUS

Andrea Hess, Justin K. Davis, Michael C. Wimberly

South Dakota State University, Brookings, SD, United States

Despite originally being a tropical disease, the highest incidence rates of human West Nile virus (WNV) within the United States are found in the cold and temperate Northern Great Plains, specifically in South Dakota. Disease transmission depends on complex interactions between the mosquito vector, the bird hosts, and humans, and is therefore highly variable in space and time. Understanding the spatial patterns of these interactions and being able to identify disease transmission hotspots are crucial for effective disease prevention and mosquito control. In this study, we used geospatial environmental data and machine learning techniques to assess the environmental drivers of human WNV cases in South Dakota and to map relative infection risk across the state. The binary dependent variable was derived from geocoded human cases from the years 2004 to 2016 and population weighted pseudo-absence points. We compared different environmental datasets to study their associations with the spatial pattern of cases. We used MODIS satellite data derived indices, such as the normalized differenced vegetation index (NDVI) and the normalized differenced water index (NDWI), as well as climatic data from the National Land Data Assimilation System (NLDAS). These remote sensing and climate datasets were both summarized over the 12 years of case data availability. We also used static environmental datasets, such as the National Land Cover Dataset (NLCD), National Wetland inventory (NWI), National Elevation Dataset (NED) and Soil Survey Geographic Database (SSURGO). We used a boosted regression tree model to identify the most important variables driving WNV risk. We generated a risk map by applying this model across the entire state. We found that inter-annual variation in humidity, temperature and surface water conditions were the strongest drivers of transmission risk. Land covers such as grasslands, low developed areas and wetlands were also found to be associated with human WNV risk. We suggest that combining measures of inter-annual environmental variability with land cover data can help to create improved disease transmission risk maps.

1640

SURVEILLANCE OF FLAVIVIRUSES IN MOSQUITOES, CARIBBEAN REGION OF COLOMBIA, 2017-2018

Salim Mattar[1], María Atencia-Pineda[1], Hector Contreras[1], Joel Montgomery[2], Stephanie Salyer[2], Nicholas Komar[3]

[1]Universidad de Córdoba, Montería, Colombia, [2]Centers for Disease Control and Prevention, Atlanta, GA, United States, [3]Centers for Disease Control and Prevention, Fort Collins, CO, United States

The emergence of Zika virus (ZIKV) in the Americas, and its association with newborn microcephaly and Guillain-Barré syndrome have raised global concern. We aimed to detect ZIKV in mosquitoes of Coloso (Sucre), Colombia to determine if novel species of mosquitoes could carry ZIKV. We trapped peridomestic and sylvatic mosquitoes using *CDC-light*, *BG-sentinel*, and *resting traps* during the months of February, May, and September, 2017, and January, 2018. We extracted viral RNA from mosquito pools (organized by species, subsite and month), and screened all pools for flaviviruses by qRT-PCR with PF1S and PF2R-Bis primers, and tested flavivirus-positive pools for ZIKV by real-time RT-PCR. A total of 4,300 female mosquitoes were collected and grouped into 373 pools. The most abundant mosquito species collected were *Culex interrogator* (n=50 pools; 13%), *Cx. (Melanoconion) sp.* (n=41; 11%), and *Cx. declarator* (n=31; 8.3%). We found 68 or 18.2% of all pools flavivirus-positive. Positive pools were detected among *Haemagogus capricorni (*1/1*; 100%)*, *Ha. janthinomys (*1/1; *100%), Coquillettidia nigricans* (1/1; 100%), *Uranotaenia lowii* (10/10; 100%), *Psorophora ferox* (9/11; 81.8%), *Cx. (Mel.) ocosa* (12/16; 75%), *Aedes aegypti* (6/8; 75%), *Ha. equinus* (3/4; 75%), *Haemagogus sp.* (1/2; 50%), *Limatus durhamii* (3/8; 38%)*, Cx. (Mel.) sp.* (12/41; 29.3%), *Ps. columbiae* (4/15; 26.7%), *Cx. chidesteri* (3/11; 27%), *Mansonia pseudotitillans* (1/4; 25%), *Ps. (Janthinosoma) sp.* (3/12; 25%), *Ma. titillans* (1/8; 13%), *Psorophora sp*. (1/8; 13%), *Culex (Cx.) sp (3/36; 8.3%)*, *Cx. coronator* (1/19; 5%), and *Cx. declarator* (1/31; 3.2%). All the aforementioned pools were negative for ZIKV virus infection. Flavivirus-infecting mosquitoes, predominantly of the genus *Culex, Psorophora* and *Aedes*, were found to circulate in Coloso, Sucre. Although we did not find ZIKV infection in these insects, other flaviviruses were common, and will be characterized to determine public health importance. Non-human primates inhabit this area and should be evaluated as reservoirs for these viruses.

1641

ZIKA VIRUS PERSISTENCE AND VIRAL LOAD IN BODY FLUIDS OBTAINED FROM INFECTED PATIENTS

Maria E. Silva[1], Julia S. Ampuero[1], David Guerrero[2], Carrion Gladys[1], Carolina Guevara[1], Yojani Aguilar[3], Dina Popuche[1], Alfredo Huaman[1], Crystyan Siles[1], Juan Wong[4], Christopher Mores[1]

[1]Naval Medical Research Unit-6, Bellavista, Peru, [2]VYSNOVA Partners, San Isidro, Peru, [3]Hospital Santa Gema, Yurimaguas, Peru, [4]UPCH, San Martin de Porres, Peru

Since the recognition that some Zika infections can be detected in fluids other than blood (sometimes for extended periods), several studies have been performed to try to understand the prevalence and impact of this upon disease transmission. Given our access to Zika patients in Peru since 2016, we initiated an enhanced surveillance program to detect cases, and follow them over time in an effort to characterize such events. Beginning in late 2017, this program detected numerous Zika cases in Yurimaguas, Loreto, Peru. To estimate the frequency, duration and viral load shedding we implemented a prospective study whereby newly confirmed Zika cases (positive by EUA CDC Trioplex real-time RT-PCR) were enrolled for follow up. Urine, saliva, blood, serum and semen or breast milk (when available) were obtained from participants every other day during their first week of illness. Weekly samples were collected thereafter, until samples became negative twice. All samples were initially tested by real-time RT-PCR. We detected Zika RNA in urine up to 21 days (6-21 days) in some participants, whereas in paired whole blood we were able to detect Zika RNA only up to 5 days. Detection of ZIKV RNA in blood was variable with excretion times ranging from 1 to 9 days after the onset of symptoms. All samples are undergoing viral isolation procedures to confirm the presence of live virus. Results from this follow up study will contribute to our understanding of Zika transmission potential and to develop guidance for optimal sample types and collection times.

1642

ZIKA VIRUS NS1 PROTEIN MODULATES THE BARRIER FUNCTION OF HUMAN PLACENTAL EXPLANTS AND HUMAN TROPHOBLAST CELL LINES

Henry Puerta-Guardo[1], Takako Tabata[2], Matthew Pettit[2], Milena Dimitrova[1], Lenore Pereira[2], Eva Harris[1]

[1]Division of Infectious Diseases & Vaccinology, School of Public Health, University of California Berkeley, Berkeley, CA, United States, [2]Department of Cell and Tissue Biology, School of Dentistry, University of California San Francisco, San Francisco, CA, United States

Zika virus (ZIKV) was recently introduced into the Americas, causing massive epidemics, and is associated with birth defects when infection occurs during pregnancy and with neurological complications in adults. ZIKV has been shown to replicate in the human placenta, and we recently proposed two potential routes for vertical transmission of virus from mother to fetus. We have also shown that the flavivirus nonstructural protein 1 (NS1) disrupts the endothelial barrier function, leading to endothelial hyperpermeability *in vitro* and vascular leakage in mouse models. Here, we investigate the effect of NS1 proteins from ZIKV

(American strain) and the closely related West Nile virus to modulate the barrier function of human placenta explants *ex vivo* and trophoblast cell lines *in vitro*. Using chorionic villus explants from different gestational ages (7-9 weeks), we showed that recombinant ZIKV NS1 but not WNV NS1 increases the permeability of explants after 24 hours of treatment, as determined by the amount of fluorescently labeled-dextran (Dx-A680) detected inside chorionic villi. Further, explants exposed to unpurified ZIKV or purified ZIKV plus ZIKV NS1 protein showed significantly more permeability compared to explants exposed to purified ZIKV alone (no NS1). In vitro permeability experiments measuring trans-epithelial electrical resistance (TEER) across human trophoblast cell lines (JAR) cultured on transwell inserts indicate that ZIKV NS1 also modulates the barrier function of these polarized cell monolayers. Ex vivo and *in vitro* studies are ongoing to define the role of ZIKV NS1 in virus dissemination and infection of target cells either in the villus core of human villus explants or human monocytic cells plated on the basolateral side of cultured JAR monolayers in transwells. These results suggest a new potential role for ZIKV NS1 in viral transmission from mother to fetus via modulation of the placental barrier function.

ZIKA VIRUS TRANSMISSION IN SRI LANKA

Ramesh Jadi[1], Matt Collins Matt Collins[2], Enrique Guerra Enrique Guerra[1], Kizzmekia S. Corbett Kizzmekia S. Corbett[3], Dharshan De Silva Dharshan De Silva[4], Hasitha Tissera Hasitha Tissera[5], Aravinda M. De Silva De Silva[1]

[1]University Of North Carolina, Chapel Hill, NC, United States, [2]Emory University School of Medicine, Atlanta, GA, United States, [3]National Institutes of Health, Vaccine Research Center, Bethesda, MD, United States, [4]Kotalawela Defense Academy, Sri Lanka, Sri Lanka, [5]Epidemiology Unit, Ministry of Health, Sri Lanka

Zika virus (ZIKV) is a mosquito borne Flavivirus that has garnered broad international attention in 2015-2016 as it rapidly spread through Latin America, causing severe birth defects and neurological disease. While the ZIKV case burden has decreased, many critical questions remain. The epidemiology of ZIKV in Asia is an area of uncertainty with major implications for understanding the recent epidemic in Latin America. While ZIKV activity is reported in many countries in the Asian continent, the complete epidemiology and patterns of transmission have not been well-defined. We employed advanced serologic techniques such as antibody depletion and micro neutralization to assess type-specific antibody responses to Zika virus from archived human specimens collected from a pediatric DENV vaccine cohort study conducted between 2008-2010 in Sri Lanka. Preliminary results demonstrate past and ongoing ZIKV transmission in the cohort. We will present data on the age specific seroprevalence and annual incidence of Zika virus infection in the cohort. We will discuss the implication of our data for understanding the Zika virus activity in the Indian sub-continent.

1644

EVALUATION OF ZIKV POTENTIAL TO INFECT VERTEBRATES AND MOSQUITOES IN AN URBAN-SYLVATIC INTERFACE IN COLOMBIA

Camila Gonzalez[1], Andres Link[2], Cielo Leon[1], Silvia Rondon[1], Juliana Hoyos[1], Nick Komar[3], Stephanie J. Salyer[4], Joel Montgomery[4]

[1]Centre for Research in Tropical Microbiology and Parasitology (CIMPAT), Department of Biological Sciences, Universidad de Los Andes, Bogota, Colombia, [2]Department of Biological Sciences and School of Management. Universidad de Los Andes, Bogota, Colombia, [3]Arbovirus Diseases Branch, Division of Vector-Borne Diseases, National Center for Emerging and Zoonotic Infectious Diseases, Centers for Disease Control and Prevention, Fort Collins, CO, United States, [4]EISL Branch, Division of Global Health Protection, Center for Global Health, CDC-Atlanta, Atlanta, GA, United States

Despite Zika virus (ZIKV) being zoonotic in origin, there is not much information about animal reservoirs for ZIKV in the Americas, and the role they might play in the virus maintenance and transmission. The aim of this study was to evaluate the potential of ZIKV to establish a sylvatic transmission cycle in Santander, Colombia. We conducted active surveillance of mosquitoes, native primates, as well as other non-human sylvatic vertebrates in the locality of Bocas del Carare, at established field sites in both urban and sylvatic areas during 50 nights. We performed fieldwork during five periods between March 2017 and March 2018. Trapping efforts were focused on abundant wildlife and domestic animals, as these likely have a role as reservoirs or amplifiers if they are hosts. We collected 24 mosquito species belonging to 10 genera, including *Aedes aegypti* as well as other suspected genus such as *Mansonia, Culex* and *Coquilletidia.* We obtained around 350 urban and 250 sylvatic samples including domestic animals, livestock and poultry, as well as wild animals belonging to classes Mammalia, Reptilia and Amphibia. Whole blood and mosquito samples were screened for ZIKV antigen by panflavivirus PCR and confirmed by a ZIKV specific PCR. Preliminary testing results revealed that 20% of vertebrates were positive by the panflavivirus PCR while no positives for mosquito pools were obtained. Remaining laboratory analysis and confirmatory testing is underway. The limited study data analyzed to date shows no evidence of the establishment of a ZIKV sylvatic cycle in Colombia. Once all data are examined and analyzed, the results of this study will directly contribute to the scientific literature by facilitating a better understanding of ZIKV's ability to establish a sylvatic cycle outside of the abundant human transmission.

1645

INCIDENCE OF GUILLAIN-BARRÉ SYNDROME IN LATIN AMERICA AND THE CARIBBEAN FOLLOWING THE 2015-2016 ZIKA EPIDEMIC

Ariadna Capasso[1], Dorice L. Vieira[2], Yesim Tozan[1]

[1]New York University College of Global Public Health, New York University, New York, NY, United States, [2]New York University School of Medicine, New York University Langone Medical Center, New York, NY, United States

Guillain-Barré syndrome (GBS), a severe autoimmune disorder, is the most common cause of acute flaccid paralysis. Between 20%-30% of patients require mechanical ventilation. Mortality rates range from 3%-7% and are higher in low-resource settings. The median global incidence of GBS is estimated at 1.1/100,000 (range 0.8-1.9). However, this is based on studies from Europe and North America. Many countries reported increases in GBS cases following the 2015-2016 Zika epidemic. Recent data from Latin America and the Caribbean (LAC) present an opportunity to assess the GBS incidence in the region for the first time. We conducted a systematic review of the incidence of GBS and searched 9 scientific databases from 1980-2017 using pre-defined search-terms. We included publications reporting primary GBS incident cases within well-defined populations. A detailed protocol is available at PROSPERO (CRD42018086659). Of 6568 identified publications, we screened 4093 titles/abstracts after removing duplicates; of 118 full-text articles reviewed, 24 met inclusion criteria. The majority (62.5%, n=15) was published after 2015. While 3 were multi-country studies; 7 were from Caribbean, including Puerto Rico; 7 from Brazil; 5 from other South American countries; and 2 from Central America and Mexico. Six analyzed the incidence of GBS in children and 2 in adults only. Sources of data included national surveillance systems (GBS disease became notifiable in 2016), hospitalization records, and the Polio Eradication Surveillance System. Background rates of GBS varied from 0.3 per 100,000 persons in Natal, Brazil to 2.65 in El Salvador and 1.31 in Honduras. GBS incidence rates increased 2 to 9.8 times from baseline during the Zika epidemic. Trends were inconclusive for chikungunya and dengue. This is the first review summarizing the GBS incidence in LAC. Central American countries appear to have higher background incidence rates of GBS than the Southern

Cone and the Caribbean. GBS incidence seems to increase during arboviral epidemics, particularly Zika. GBS poses an additional burden to healthcare systems, particularly in low-resource settings.

1646

ZIKA VIRUS INFECTION IN OLIGOSYMPTOMATIC AND ASYMPTOMATIC CLOSE CONTACTS IN PERU

Julia S. Ampuero[1], Yojani Aguilar[2], David Guerrero[3], Crystyan Siles[4], Maria Silva[1], Carolina Guevara[1], Sarah Jenkins[1], Juan Wong[5], Wesley Campbell[1], Joel Montgomery[6], Christopher Mores[1]

[1]U.S. Naval Medical Research Unit No. 6 (NAMRU-6), Lima, Peru, [2]Hospital Santa Gema de Yurimaguas, Ministerio de Salud del Perú, Yurimaguas, Peru, [3]VYSNOVA Partners, Lima, Peru, [4]U.S. Naval Medical Research Unit No. 6 (NAMRU-6), Iquitos, Peru, [5]Universidad Peruana Cayetano Heredia (UPCH), Lima, Peru, [6]Centers for Disease Control and Prevention (CDC), Atlanta, GA, United States

The first Zika virus (ZIKV) infection was detected in Peru in February 2016. As of epidemiological week 7 of 2018, 441 cases of Zika have been reported in the country, 210 cases less than the previous year for the same period of time. Given that approximately 80% of cases are asymptomatic, there is potentially a significant level of underreporting in this data. In an effort to account for this, the aim of this study was to determine the prevalence of ZIKV infection in asymptomatic or oligosymptomatic close contacts of confirmed ZIKV infection through cluster investigations. This study was nested in a surveillance of febrile and exanthematous acute illness in Yurimaguas (lat -5.92; long -76.09), a Peruvian Amazon city with approximately 68,115 habitants. When a ZIKV infection was detected and the participant allowed informing their laboratory results to their household contacts, the participant was visited in their house. The household close contacts were defined as persons who have been living in or around the same house for the last 30 days. We invited all close contacts older than 5 years old to participate in the study. We followed each house weekly for 21 days. After the informed consent was obtained, if any sign or symptom suggested active infection, we took a 10 mL blood sample. If we found no symptoms, we obtained a 2 mL blood sample. All samples were processed by Trioplex Real-time RT-PCR Assay (CDC). Since December 2017 to March 2018 we detected 20 ZIKV infections, from those 16 clusters were identified with 37 household close contacts enrolled. ZIKV infections were found in 2 from 6 oligosymptomatic and 4 from 31 asymptomatic participants. Two asymptomatic ZIKV positives developed symptoms two days after the enrollment. Our study shows that the number of ZIKV cases is greater than those observed in the health facilities, which could range from 13% in asymptomatic cases to 33% in oligosymptomatic ones among the index case close contacts.

1647

ARBOVIRUS CO-INFECTIONS PROLONG DISEASE DURATION AND DELAY VIRAL CLEARANCE

Marta G. Cavalcanti, Eduardo S. Pimenta, Mauro Jorge Cabral-Castro, Jose Mauro Peralta

Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

ZIKV and CHIKV co-infections (ZIKV/CHIKV CO) occur at variable rates in areas of arbovirus co-transmission. Nonetheless, there are scarce data on clinical and virological findings during long-term follow–up. 23 laboratory-confirmed ZIKV and CHIIKV co-infected individuals were followed – up for two years. Short duration disease (ZIKV/CHIK CO short) was defined as ≤ 13 days post-onset (do) and prolonged (ZIKV/CHIK CO pro) as > 14 do. RT-PCR for detection of ZIKV and CHIKV RNA was performed in serial samples of sera, whole blood and urine longitudinally collected. Demographic findings included nine female and 14 male (mean age of 48.8 ± 12.7 years old). In 6 /23 (26.1%) individuals, ZIKV/CHIK CO presented as a short (mean: 8.3 ± 4.5 do; 95% CI: 3.563-13.1) and, 18/23 (78.26%) a prolonged duration disease (mean: 95.1 ± 78.96 do; 95% CI: 54.52-135.7). Comparison between groups showed a statistically significant difference ($p < 0.0001$). Viral clearance assessed by RNA detection showed that ZIKV clearance occurred in 11 ± 6.54 days (95% CI: 10.2 – 88.2) in ZIKV/CHIK CO short and, 49.2 ± 70.5 days (95% CI: 4.134-17.87), in the prolonged duration infection group ($p < 0.015$). CHIKV clearance extended for 31.8 ± 29.6 (95% CI: 16.03-47.59) and 10 ± 7.95 days (95% CI: 1.657-18.34) in the ZIKV/CHIK CO prolonged and short duration disease, respectively ($p < 0.05$). Arbovirus co-infections present as short and prolonged duration diseases. In the last group, co-infection delays both ZIKV and CHIKV clearance in serum or urine. Prolonged ZIKV/CHIK CO might contribute to progression to chronic ZIKV infection.

1648

CO-CIRCULATION AND CLINICAL MISDIAGNOSIS OF ZIKA, DENGUE, AND CHIKUNGUNYA LED TO UNDERESTIMATION OF THE 2015-2016 ZIKA EPIDEMIC IN THE AMERICAS

Rachel J. Oidtman, Guido España, Alex Perkins

University of Notre Dame, Notre Dame, IN, United States

During the 2015-2016 Zika epidemic, two other arboviruses - dengue and chikungunya - were also in circulation in many countries in the Americas. Published results from a clinical study in northeastern Brazil showed that clinical case definitions used throughout the region at this time were highly prone to misdiagnosis, due to imperfect sensitivity (all < 87%) and specificity (all < 79%). Given the importance of clinical surveillance data for informing estimates of the epidemic's dynamics, our aim was to produce revised estimates of the magnitude of the Zika epidemic in light of clinical misdiagnosis in areas with co-circulation of two or more of these viruses. Our approach was based on a series of equations that define fundamental mathematical relationships among the numbers of disease episodes attributed to each of these three viruses on the basis of case definitions and the numbers of disease episodes that truly were caused by each of these three viruses. Using these relationships, we identified combinations of diagnostic sensitivity and specificity that were compatible with weekly case reports of all three diseases at a national level from 2014-2017 across all PAHO countries. For each country, this yielded a probabilistic estimate of the weekly incidence of symptomatic cases that truly were caused by each of Zika, dengue, and chikungunya viruses. Of the nearly 8 million cases of dengue and chikungunya reported in the Americas in 2014-2017, we estimate that 319,730 (95% CI: -364,141-1,440,888) may have been caused by Zika virus (ZIKV) infection instead. This implies an 80% chance that at least some portion of reported dengue and chikungunya cases were caused by ZIKV infection. Across the region as a whole, these findings revise estimates of the Zika epidemic from 745,572 to 1,137,302 cases. The majority of these misdiagnoses come from countries with high incidence of all three viruses. These findings have significant implications for quantifying the magnitude and spatial distribution of ZIKV infections, which is of critical importance for projecting risk of future Zika epidemics in the Americas and for planning prospective cohort studies.

VACCINATION FOR JAPANESE ENCEPHALITIS IN THE PHILIPPINES: A COST-EFFECTIVENESS ANALYSIS

Elisabeth Vodicka[1], Anna Lena Lopez[2], Maria Wilda Silva[3], Leonita Gorgolon[4], Toda Kohei[5], Marita Zimmermann[6], Jessica Mooney[1], Clint Pecenka[1], Anthony A. Marfin[1]

[1]PATH, Seattle, WA, United States, [2]University of Philippines, Manila, Manila, Philippines, [3]Department of Health, Manila, Philippines, [4]Department of Health, Pampanga, Philippines, [5]World Health Organization, Country Office, Manila, Philippines, [6]Consultants in Global Health, LLC, Seattle, WA, United States

Japanese Encephalitis (JE) is a mosquito-borne viral infection causing a type of "brain fever," especially in children. JE kills up to 30% of victims and leaves up to half of survivors with permanent brain damage. In the Philippines, efforts are underway to provide a safe and efficacious live

attenuated JE vaccine (CD-JEV) to children through a national vaccination routine immunization (RI) strategy. To inform decision-making, the cost-effectiveness of JE vaccination was compared to a strategy of no vaccination. A Markov model was developed from the payer perspective to assess potential health outcomes and costs associated with introduction of CD-JEV, assuming 82% coverage and 93% efficacy. The model simulated a child from time of vaccination or no vaccination through five health states (no JE, acute JE, asymptomatic JE, post-acute JE, and death) over one-year cycles. Costs of illness ($859/acute care case), vaccines ($0.50/dose), and routine service delivery ($0.95/dose) were established via in-country clinical and financial records from local government programs and health facilities. Transition probabilities and incidence data were derived from literature with a base case incidence of 10.6/100,000. Disability weights were applied to consider quality of life, and costs and outcomes were discounted at 3%. One-way and probabilistic sensitivity analyses evaluated model uncertainty. Model results suggest that CD-JEV introduction is likely to be highly cost-effective compared to no vaccination when introduced via RI with a cost per life year saved of $182 (95% credible range [CR]: $46-$315). Cost-effectiveness ratios below per capita gross domestic product are often viewed favorably, and this value is only 6% of per capita gross domestic product. Vaccination was estimated to cost $1,233/averted JE case (95% CR: $383-$2544), $150/disability adjusted life year averted (95% CR: $55-$397) and $7,200/death averted (95% CR: $2,068-$16,418). In general, implementation of JE vaccination through a routine immunization strategy is predicted to improve health outcomes for the population and reduce long term costs due to JE cases averted.

RAPID DIAGNOSIS OF CHIKUNGUNYA VIRUS BY MOLECULAR TECHNIQUES RT-PCR AND RT-LAMP IN FEBRILE PATIENTS FROM MACHALA, ECUADOR AND TUMBES, PERU

Cinthya Cueva Aponte[1], Emmerik Motte[2], César Santos Chanta[3], Dariel Díaz Arce[4], Anna M. Stewart-Ibarra[5]

[1]SUNY Upstate Medical University, Machala, Ecuador, [2]Universidad Nacional de Tumbes, Tumbes, Peru, [3]Empresa de Investigación y Capacitación en Biotecnología Inca'Biotec S.A.C., Tumbes, Peru, [4]Unidad Educativa Santana, Cuenca, Ecuador, [5]SUNY Upstate Medical University, Syracuse, NY, United States

Chikungunya, along with other tropical diseases such as dengue and zika, is a global level public health issue transmitted via bites from mosquitos of the genus *Aedes aegypti* and *A. albopictus.* Not all diagnostic laboratories have access to molecular testing based in PCR. The present work consisted of the implementation of the isothermal amplification technique "RT-LAMP" and its comparison to RT-PCR, the technique used in the diagnosis of chikungunya. For this analysis, 16 serum samples were taken from febrile patients suspected to have chikungunya infections in Machala, Ecuador and Tumbes, Peru. Serum samples were screened via RT-PCR for the chikungunya gene fragment viral glycoprotein E1 (401pb). Samples were sent for sequencing and virus strains were found to be homologous to Caribbean genotypes (99%) as well as, to a less degree, to those of Africa (94% Congo), India (93%) and Brazil (93%). RT-PCR revealed 5 positives cases (31.25%) while RT-LAMP detected 11 positive cases (68.75%) in the 16 serum samples analyzed. In conclusion, the technique RT-LAMP was revealed to be applicable in the diagnosis of serum samples of patients from the Ecuador-Peru region with symptoms of mosquito-borne viruses. This fast, sensitive and specific test can be rapidly implemented in any diagnostic laboratory thus improving said laboratory's capacity to detect viruses in patients.

1651

IMPACT OF JAPANESE ENCEPHALITIS VACCINE INTRODUCTION, UTTAR PRADESH, INDIA, 2006-2017

Dipti Rai[1], Shalini Khare[2], Jessica Mooney[3], Pradeep Haldar[4], PK Sen[5], Arun Prakash Chaturvedi[6], Mitilesh Chaturdevi[7], Anthony A. Marfin[3], Joseph Zunt[1], Lisa Manhart[1], G William Letson[3]

[1]University of Washington, Seattle, WA, United States, [2]PATH, New Delhi, India, [3]PATH, Seattle, WA, United States, [4]Expanded Program on Immunization, Ministry of Health, India, New Delhi, India, [5]National Vector Borne Disease Control Program, India, New Delhi, India, [6]Immunization Program, Uttar Pradesh, India, Lucknow, India, [7]Vector Borne Disease Control Program, Uttar Pradesh, Lucknow, India

Japanese encephalitis (JE) virus is the leading cause of viral neurological disease and disability across temperate and tropical zones of Asia. Several vaccines exist to prevent JE disease, including the live attenuated SA-14-14-2 Japanese encephalitis vaccine (CD-JEV) manufactured by the Chengdu Institute of Biological Products (CDIBP). Previous trials with CD-JEV have shown that it is safe and effective. India introduced CD-JEV in 2006, in selected states, and eventually expanded to national use in routine immunization (RI). Efforts to measure the impact of CD-JEV introduction in Uttar Pradesh (UP), India, one of the first states to introduce CD-JEV, was assessed by analyzing immunization data in comparison to serum and/or CSF IgM Elisa-confirmed JE disease in seven high-risk districts of UP. Vaccination data assessed included campaigns targeting children 1-15 years old, and RI targeting 9-12 month olds in these districts annually. Analysis showed that JE incidence dropped from 43/1,000,000 in 2010 to near 0 in 2011, and then varied from 15-7/1,000,000 in the period 2012-2016. JE vaccine RI coverage ranged 10-60% over this period. Campaigns in these seven districts in 2006 and 2010 reached >95% coverage and are likely responsible for most of the decline in disease incidence. Data analysis for three other district clusters that conducted single JE vaccination campaigns in 1-15 year olds in 2007, 2008, and 2009, reached over 90% coverage, followed by RI coverage between 22-60%. Analysis of immunization efforts in each of these three clusters failed to show an impact on disease, unlike the initial district cluster. However, linear regression analysis of JE incidence trends in all 36 districts demonstrated a significant decline overall (p=0.00001). We conclude that a single campaign with high coverage followed by low RI coverage is not sufficient to reduce JE occurrence without catch-up campaigns.

1652

*A*SSESSING THE IMPACT OF HOUSE ABANDONMENT ON *AEDES AEGYPTI*-TRANSMITTED DISEASE RISK TWO YEARS AFTER THE 2016 EARTHQUAKE IN BAHÍA DE CARÁQUEZ, ECUADOR

Avriel Diaz[1], Anna M. Stewart-Ibarra[2], Marco Neira[3], David Macias[4], Maria Diuk-Wasser[1]

[1]Department of Ecology, Evolution, and Environmental Biology (E3B), Columbia University, New York, NY, United States, [2]SUNY Upstate Medical University, Syracuse, NY, United States, [3]Centro de Investigación para la Salud en América Latina (CISeAL), Pontificia Universidad Católica del Ecuador, Quito, Ecuador, [4]Ministerio de Salud Publica, Bahía de Caráquez, Ecuador

In 2016, a devastating earthquake (magnitude 7.8) struck the province of Manabí in coastal Ecuador, resulting in severe destruction, morbidity and mortality. Following the disaster, the risk of *Aedes aegypti*-transmitted illnesses (e.g., dengue, chikungunya, Zika) increased due to damaged housing, increased water storage, increased exposure to infectious mosquito bites, and limited access to healthcare. Following the earthquake, a major epidemic of Zika fever occurred, with 85% of cases in Ecuador reported within 100 km of the earthquake epicenter. Zika is a global health concern because it can cause a spectrum of congenital

complications. Two years after the earthquake, many damaged homes have been abandoned at the edges of inhabited communities, and these areas do not receive mosquito control by the public health sector. We hypothesize that abandoned areas have greater vegetation cover and shade, and provide larval habitat and refuge for adult *Ae. aegypti* in 3 urban and 3 periurban sites in Bahía de Caráquez, Ecuador. Here, we examine the effect of the spatial distribution of abandoned homes in a post-disaster scenario, vegetation cover and neighborhood housing conditions on larval habitat, average number of mosquito larvae/pupae/adults per site, and the prevalence of arboviruses (identified by RT-PCR) in pools of adult *Ae. aegypti*. These findings improve our understanding of how abandoned sites following natural disasters may amplify human arbovirus infection risk, information that will inform interventions to reduce the risk of infectious diseases in affected communities.

1653

USE OF DISPERSION INDEX TO IDENTIFY KEY CONTAINERS RESPONSIBLE FOR *AEDES AEGYPTI* BREEDING IN SELECT COMMUNITIES OF GUATEMALA

Julie Buekens[1], Julie Niemczura de Carvalho[1], Megan Perry[1], Jose Ernesto Monzon[2], Arturo Sanchez[2], Juan Arredondo[3], Luis Benavente[1]

[1]Medical Care Development International (MCDI), Silver Spring, MD, United States, [2]Medical Care Development International (MCDI), Guatemala City, Guatemala, [3]Independent, Guatemala City, Guatemala

As part of the Zika Community Response (ZICORE) project in Guatemala, we quantified household containers that could become *Aedes aegypti* breeding sites in order to gather entomological data to target Zika prevention and control interventions. As the water supply fluctuates, households store water and often have non-useful containers outside where rain water also accumulates. In 2017, a round of pupal surveys was conducted in 32 Guatemalan communities. Water containers were inspected for *Aedes* larvae or pupae, which were counted when present. A dispersion index (DI) was used to determine if the sample size needed adjustment. A total of 821 households (HHs) were visited, 40% of which contained pupae (HH index). Use of DI allowed for basins and barrels to be identified as key breeding sites for *Aedes* in 18 out of the 32 communities visited. Small and medium containers kept in the front yards or backyards were identified as key breeding sites in 8 communities. Used tires kept outdoors were identified as key breeding sites in 3 communities. These data were used to guide the implementation of social and behavior change communication and community mobilization activities to reduce or eliminate key containers, such as mass disposal of used tires in targeted communities. In contrast to other indices, DI was used to effectively determine container productivity and identify key *Aedes* breeding sites that needed to be targetedand removed. Such data-driven vector control activities have the potential to increase cost effectiveness and impact in the reduction of Zika transmission.

1654

EVALUATION OF COMMUNITY-LEVEL VECTOR CONTROL ACTIVITIES AND *AEDES AEGYPTI* EGG DENSITY INDICES IN GUATEMALA

Megan Perry[1], Julie Buekens[1], Julie Niemczura de Carvalho[1], Jose Ernesto Monzon[2], Arturo Sanchez[2], Juan Arredondo[3], Luis Benavente[1]

[1]Medical Care Development International (MCDI), Silver Spring, MD, United States, [2]Medical Care Development International (MCDI), Guatemala City, Guatemala, [3]Independent, Guatemala City, Guatemala

The Zika Community Response (ZICORE) project in Guatemala aims to improve surveillance of the *Aedes* vector by using entomological data as the basis for low-cost community-level vector monitoring as well as social and behavior change interventions. In 2017, household-level *Aedes aegypti* breeding site monitoring was conducted in 44 communities. Ovitraps were installed in selected households and egg counts were recorded weekly. In these communities, 4,457 trap readings were positive out of 8,004 readings. A moving average was used to adjust for seasonality to enhance vector monitoring and identify communities of high entomological risk to be targeted for community-level clean-up campaigns. Utilizing weekly ovitrap monitoring results, the ZICORE project has implemented community-level campaigns to prevent *Aedes aegypti* breeding, such as: -Breeding sites eliminated in targeted communities in the 90th percentile or above for ovitrap egg counts. Activities included disposal of non-useful containers and scrubbing of sinks and useful containers as part of the ZICORE-VELITA (*Voltear, Eliminar, Limpiar y Tapar*) protocol, which describes in Spanish the steps to be taken with household items that have the potential to become mosquito breeding sites (in English: flip, eliminate, clean and cover). -Elimination of solid waste identified as potential *Aedes* breeding sites, including tires and non-useful containers of varying sizes. Included strong municipal government support, such as sponsored trash removal vehicles to dispose of waste. Communities below the 90th percentile for ovitrap egg counts did not receive intensified community-level interventions and will be analyzed as controls. This analysis is useful for assessing any correlation between community-led clean-up campaigns and *Aedes aegypti* egg counts in intervention versus control communities.

1655

URBANIZATION INCREASE THE POPULATION ABUNDANCE OF EARED DOVE (*ZENAIDA AURICULATA*), AMPLIFYING HOST OF ST. LOUIS ENCEPHALITIS VIRUS (SLEV, FLAVIVIRUS)

Giovana Peralta[1], Guillermo Albrieu-Llinás[2], Mauricio Beranek[2], Susan Peluc[1], **Adrian Diaz**[2]

[1]Instituto de Diversidad y Ecología Animal (IDEA), CONICET - Universidad Nacional de Córdoba, Córdoba, Argentina, [2]Instituto de Virología "Dr. J. M. Vanella", Facultad de Medicina. Universidad Nacional de Córdoba, Córdoba, Argentina

Human-ecosystem interactions have changed in the last 10.000 years producing a greater environmental invasion and changes in the use of land cover for the exploitation of natural resources. Among the immediate environmental effects we can refer to global climate change, habitat alteration, changes in the assembly of species and their human interchange that promote the emergence of zoonotic diseases. In Argentina, SLEV emerged as a human pathogen since 2005 when a human encephalitis outbreak occurred in Córdoba city. Eared Dove (*Zenaida auriculata*) and *Culex quinquefasciatus* mosquito are the main host and vector species, respectively. The main goal of this study was to evaluate the effect of urbanization over the abundance and production of nests of Eared Dove. Using Landsat 8 satellite images of high-resolution, indexes related to urban landscape (i.e. indicators of built surface, vegetation and productivity, bodies of water, complexity and dominance of landscape elements) were obtained. Córdoba city area was classified into three levels of urbanization (high, medium and low). Abundance of Eared Dove and number of nests were recorded in fixed-width transects in 30 randomized sites in the city (10 for each urbanization level). The distribution of the abundance was analyzed by a Generalized Linear Model (GLM) with negative binomial distribution of errors, log link function. The statistical significance (α= 0.05) of the terms was determined through ANOVA. Built surface was the only tested variable that explained significantly the abundance of Eared Dove. On the other hand, the variable nests of Eared Dove was significantly explained by built surface, high vegetation and distance between low grasses. Our study reveals a positive effect of urbanization over the abundance of Eared Dove. Eared Dove represents the second most abundant bird species and produces 15 times more SLEV infectious mosquitoes than other bird species. The expansion and colonization of urban areas by Eared Dove can be one of the factors causing the emergence of SLEV in Argentina.

1656

FITNESS OF ZIKA VIRUS MUTATIONS CIRCULATING IN THE AMERICAS

Glenn Oliveira[1], Sharada Saraf[1], Carlos Ontiveros[1], Rimjhim Agarwal[1], Greg D. Ebel[2], Nathan D. Grubaugh[3], Kristian G. Andersen[1]

[1]The Scripps Research Institute, Encinitas, CA, United States, [2]Colorado State University, Colorado Springs, CO, United States, [3]Yale, New Haven, CT, United States

The recent Zika virus (ZIKV) epidemic spread throughout the Americas and infected millions of people causing severe fetal and neurological disease. The emergence of similar mosquito-borne RNA viruses like West Nile and chikungunya has been attributed to genetic adaptations to their environment, but the dramatic spread of ZIKV, and the origin of it's disease severity remain unexplained. While there have been recent publications describing the functional effects of ZIKV NS1 and prM mutations, there has yet to be a comprehensive study to determine the effects of genetic variants which arose during the ZIKV outbreak, and whether or not they alter viral fitness. Our preliminary data comparing replicative and competitive fitness between ZIKV isolates collected throughout the Americas demonstrated phenotypic variability, suggesting a genetic component. To further test this hypothesis, we reverse engineered 12 clade-specific ZIKV genetic mutations detected during the epidemic into a recent ZIKV isolate (PRVABC-59). We will evaluate the replicative fitness of each mutation across several relevant primary and continuous human, primate, and mosquito cell lines. In addition, we will use competitive fitness assays to detect subtle functional differences of individual mutations against the infectious clone containing the wild type sequence. Finally, we will infect *Aedes Aegypti* mosquitoes to detect mutations that influence vector competence and transmission. Our proposed system will provide insights into the genetic determinants of Zika virus disease and emergence. Moreover, the studies outlined here will provide a framework for evaluating functional virus evolution during disease outbreaks.

1657

ENABLING HEALTHCARE ACCESS FOR HEPATITIS C THROUGH COMMUNITY-BASED SCREENING AND LINKAGE TO CARE

Austin T. Jones, Keanan M. McGonigle, Tess F. Carley, Linda Nix, Morris M. Kim, Sonal G. Mallya, Meaghan O. Coyne, Frances Lee, Joseph M. Kanter, Patricia Kissinger, Latha Rajan

Tulane University, New Orleans, LA, United States

Although HIV has received great attention, a parallel epidemic - that of HCV - has been ignored until recently. Globally, HCV infects 71 million people and causes 400,000 deaths annually. New Orleans is currently suffering from a Hepatitis C epidemic comparable to regions with the highest prevalence of HCV worldwide. This disease disproportionally affects marginalized populations who lack healthcare access. With 80% of infected individuals unaware of their diagnosis, early detection is the primary barrier to eradicating this silent epidemic. This project seeks to address this shortcoming by bringing screening directly to the community, focusing on high-risk individuals. The aim of this project is to improve access to timely healthcare by linking HCV infected individuals to a network of specialist treatment. The study site includes community-based medical student run clinics in the city of New Orleans. The impact of our program will be presented based on outcome measures including detected HCV prevalence, linkage to care rates, and the number of patients successfully cured. Voluntary HCV screening using a rapid antibody test began in March 2015 and has now expanded to include eight homeless shelters, food pantries, and rehabilitation facilities across Orleans Parish. The patient-centered medical home model is utilized to coordinate care across multiple specialty services. Patient navigators guide our vulnerable population through the complex treatment cascade and maximize linkage to care. From March 2015 to April 2017, 245 (28%) of 861 patients screened have tested HCV positive. Of the 221 patients currently in our treatment cascade, 131 are RNA confirmed and 83 have received a hepatic ultrasound. Ten patients have begun treatment and four are cured of HCV. The most up-to-date results will be presented. Our program can provide "lessons learned" to the audience as a model for screening marginalized populations, and in addition, coordinating their care through a multi-step evaluation and treatment cascade. This model could be replicated elsewhere to improve healthcare access by bringing services directly to a community in need.

COINFECTION OF PLACENTAS FROM CONGENITAL ZIKA VIRUS INFECTION WITH HUMAN CYTOMEGALOVIRUS IN BABIES WITH AND WITHOUT MICROCEPHALY

Lenore Pereira[1], Matthew Petitt[1], Anna Gajewski[2], June Fang-Hoover[1], Liliam Llufrio[2], David Schwartz[3], Angel Balmaseda[4], Eva Harris[5]

[1]Department of Cell and Tissue Biology, School of Dentistry, University of California San Francisco, San Francisco, CA, United States, [2]Sustainable Sciences Institute, Managua, Nicaragua, [3]Medical College of Georgia, Augusta University, Augusta, GA, United States, [4]Laboratorio Nacional de Virología, Centro Nacional de Diagnóstico y Referencia, Ministry of Health, Managua, Nicaragua, [5]Division of Infectious Disease and Vaccinology, School of Public Health, University of California Berkeley, Berkeley, CA, United States

Zika virus (ZIKV), a mosquito-borne flavivirus, caused the 2015-2016 epidemic linked to severe birth defects in Brazil and Central America, countries where over 95% of the population is seropositive for human cytomegalovirus (HCMV), a herpesvirus that also causes congenital infection and disease. Spread of maternal infection to the fetus can result in congenital ZIKV syndrome (CZS), a spectrum of neurological and neuromuscular defects including microcephaly. ZIKV RNA is detected in the brains, placenta and amniotic fluid of affected babies. Whether HCMV is a co-factor that could contribute to severe congenital anomalies has not been studied. We reported that Nicaraguan ZIKV strains infect cytotrophoblasts in cell columns, Hofbauer cells (fetal macrophages) in villus cores of anchoring villi from explants of first-trimester placentas and primary amniotic epithelial cells, suggesting routes of transmission. Here we examined placentas from 19 cases of congenital ZIKV infection from the Nicaraguan Zika Positives Study of pregnant women confirmed as rRT-PCR ZIKV+ by the Ministry of Health or with positive serology and history of Zika symptoms during pregnancy. Fetal diagnosis was confirmed at delivery and follow-up of infants is ongoing. Over 100 biopsy specimens from chorionic villi, basal and parietal decidua and amniochorionic membranes were examined for ZIKV antigens and pathology. Fifty-five specimens were also immunostained for HCMV antigens. Immunohistochemistry detected ZIKV NS3 protein in cells in basal and parietal decidua, the chorion and occasionally villus cores. HCMV antigens were also found in 5 of 19 placentas, including 2 of 6 cases of microcephaly, in cells of the amniotic membranes, chorion and basal and parietal decidua. Although villitis was mostly absent, indicators of chronic vascular underperfusion, Tenney-Parker changes and villus aggregation were found. Increased Hofbauer cell densities and villus edema were observed in placentas from cases of microcephaly. Our results suggest that ZIKV and HCMV coinfection should be diagnosed and the contributions of each virus to pathology and birth defects determined.

GROWTH AND DEVELOPMENTAL OUTCOMES OF CONGENITAL ZIKA INFECTION DURING FOLLOW-UP OF A CHILD COHORT FROM SALVADOR, BRAZIL

Claudia O. Gambrah-Sampaney[1], Pablo Aguilar[2], Nivison Nery Jr.[3], Bruno Freitas[4], Joseane Bouzon[2], Ailema Guerra[3], Jamary Oliveira-Filho[2], Haritha Adhikarla[1], Magelda Montoya[5], Elsio A. Wunder Jr[1], Eva Harris[5], Mitermayer Reis[3], Federico Costa[3], Albert Ko[1]

[1]Yale School of Public Health, New Haven, CT, United States, [2]Federal University of Bahia, Salvador, Brazil, [3]Oswaldo Cruz Foundation, Salvador, Brazil, [4]Hospital Geral Roberto Santos, Salvador, Brazil, [5]School of Public Health, University of California Berkeley, Berkeley, CA, United States

A large proportion of children were exposed to Zika virus (ZIKV) during the 2015 epidemic in Northeast Brazil yet did not develop severe birth defects, such as microcephaly. To determine whether these children have adverse growth and development outcomes as they complete their 2nd year of life, we recruited a cohort of children who were born between October 2015 and January 2016 from a maternity hospital of Salvador, Brazil. We evaluated growth, development and neurological outcomes by performing anthropometric measurement, Bayley Scales of Infant Development III and Hammersmith Infant Neurological Exam (HINE), respectively. Children received clinical evaluations that included audiometry (OAE, ABBR), ophthalmological exam, and when indicated, examinations with a pediatric neurologist and imaging studies. The Blockade of Binding (BoB) assay, which uses the ZIKV35 anti-NS1 monoclonal antibody, was performed to evaluate ZIKV exposure. Among the 513 children who were born during the study period, 55 (11%) had microcephaly. Of the 458 children who were born without microcephaly, we have performed outcome measurements of 208 (45%) and have completed BoB analysis to date for 72(35%). Of these 72 children, 28(39%) had serologic evidence of ZIKV exposure. These children with serologic evidence of ZIKV exposure had an increased proportion of ophthalmologic (17% vs. 3%, p=0.105) and auditory abnormalities (12% vs. 0%, p=0.098) in comparison to the 44 without evidence of exposure, albeit these differences were not significant. We are completing follow-up of the cohort and the serological evaluations to obtain more precise estimates. Although our analyses are preliminary, these findings suggest that children who were exposed to the virus who were not identified to have defects at birth may have significant disabilities as they enter the 2nd year of life.

1660

KINETICS OF ANTI ZIKA-IGG ANTIBODIES DURING FOLLOW-UP OF INFANTS EXPOSED TO ZIKA VIRUS *IN UTERO*

Haritha Adhikarla[1], Magelda Montoya[2], Nivison Jr. Nery[3], Adeolu Aromolaran[1], Jaqueline S. Cruz[3], Andrew Pastor[2], Mary Petrone[1], Elsio A. Wunder[1], Federico Costa[3], Eva Harris[2], Albert I. Ko[1]

[1]Yale School of Public Health, Department of Epidemiology of Microbial Diseases, New Haven, CT, United States, [2]Division of Infectious Diseases and Vaccinology, School of Public Health, University of California, Berkeley, CA, United States, [3]Federal University of Bahia. Oswaldo Cruz Foundation, Brazilian Ministry of Health, Salvador, Brazil

Zika virus (ZIKV) infection during pregnancy is a cause of congenital microcephaly, which involves severe fetal brain defects and has also been associated with other adverse birth outcomes. Currently there is no validated laboratory test to detect *in utero* exposure to ZIKV in infants. Detection of IgG antibodies in infants beyond 8-months could be a proxy for ZIKV exposure *in utero*. In this study, infants who were born during a Zika outbreak (from October 1, 2015 to January 31, 2016) in Salvador, Brazil, were evaluated by ZIKV nonstructural protein 1 (NS1)-based blockade-of-binding (BOB) ELISA. The study population encompassed 234 mother-infant pairs from the General Hospital Roberto Santos (HGRS). Of 234 infants, there were follow-up longitudinal samples for 55 infants (23%). These infant longitudinal samples were further classified into four groups based on Microcephaly (MC), IgM ELISA and PCR-confirmation status at birth: MC^+ and IgM^+/PCR^+ (15 samples), MC^- and IgM^+/PCR^+ (4 samples), MC^+ and IgM^-/PCR^- (9 samples), MC^- and IgM^-/PCR^- (27 samples). The ZIKV infection status of corresponding mother samples was confirmed by Plaque Reduction Neutralization Test (PRNT) and NS1 BOB ELISA. We observed 80% positivity rate in the NS1 BOB assay for infants in the MC^+ and IgM^+/PCR^+ group while only 44% of the infants scored positive in the MC^+ and IgM^-/PCR^- group. Interestingly, the positivity rate of 55% in the MC^- and IgM^-/PCR^- group infants indicates the possibility of ZIKV exposure in these infants at a later time-point after birth. We observed that overall duration of detectable IgG antibodies against ZIKV NS1 did not wane even after disappearance of maternal antibodies (6-9 months). Our survey of infants by NS1 BOB ELISA in Salvador could help in rigorous follow-up of infants born to women with potential exposure to ZIKV. In addition, screening by NS1 BOB assay will also inform us about those cases where infants were exposed to ZIKV at later time-points. Therefore, this study helps in understanding the long-term implications of ZIKV outbreak in Salvador and also in developing appropriate care strategies for affected children.

IMPLICATIONS OF CONGENITALLY ACQUIRED AND EARLY EXPOSURE TO ZIKA VIRUS INFECTION ON CHILD NEURODEVELOPMENT

Shiara M. Ortiz Pujols[1], Eveling L. Martinez Rosales[2], Barbara D. Goldman[3], Matt Collins[1], Meylin Chavarria Tórrez[2], Leyla Rosales Quintana[2], Yaoska Reyes[2], Omar Zepeda[2], Aravinda de Silva[1], Filemon Bucardo[2], Sylvia Becker-Dreps[1], Elizabeth Stringer[1], Natalie Bowman[1]

[1]University of North Carolina at Chapel Hill, Chapel Hill, NC, United States, [2]UNAN, Leon, Nicaragua, [3]University of North Carolina at Chapel Hill/Frank Porter Graham Child Development Institute, Chapel Hill, NC, United States

The full spectrum of adverse developmental outcomes in ZIKV-exposed fetuses and infants is not fully understood. We are monitoring a prospective pregnancy cohort in León, Nicaragua to design algorithms for ZIKV surveillance in pregnant women and to better understand outcomes. Our cohort of 253 pregnant women were recruited Jan-Apr, 2017; all have given birth. Outcomes include 3 cases of documented microcephaly, 1 of anencephaly, and 3 stillbirths. At each parent-infant visit, at 3, 6, 12, & 18 months, staff collect demographic, socioeconomic, and medical data via parental questionnaires and record infant anthropometric measurements. They assess infant neurocognitive development using the Mullen Scales of Early Learning (MSEL), a validated neurodevelopmental assessment, translated into Nicaraguan Spanish. The 5 Scales assess gross & fine motor, visual reception, and receptive & expressive language. The Mullen standardized Cognitive Composite combines standardized scores from the last 4 scales. The infants will also have formal ophthalmologic & otoacoustic tests. Every 3 months, samples of the infants' blood are assayed for maternal antibody titers & incident ZIKV infections. In lab testing on the first 120 cord blood specimens, 75 (62.5%) were positive on ZIKV neutralization tests, supporting ZIKV-exposure during pregnancy. We are still compiling results of analyses of ZIKV infection status and presence/magnitude of neurodevelopmental deficits, including visual & auditory results, of these exposed/infected and unexposed infants. We use multivariate regression and analyses to estimate the mean differences in standardized T-scores for each of the Mullen Scales and the MSEL Composite between exposed/infected and unexposed infants, and to estimate the associations between the groups & the odds of scoring below average on the Composite. For multivariable analyses, we use generalized estimating equations to account for repeated observations of the same infants. The results of this prospective analysis will describe the impact of ZIKV infection/exposure on infant neurodevelopment in a way not yet done to date.

1662

EXPLORING THE DIFFERENCES IN IMMUNE RESPONSES BETWEEN SURVIVORS AND NONSURVIVORS OF *ZAIRE EBOLA VIRUS* CHALLENGE IN CYNOMOLGUS MACAQUES VACCINATED WITH A RECOMBINANT SUBUNIT BASED VACCINE

Liana O. Medina[1], Teri Ann S. Wong[1], Michael M. Lieberman[1], Alexandra Gurary[1], Thomas W. Geisbert[2], Hanne Andersen[3], Axel T. Lehrer[1]

[1]University of Hawaii at Manoa, Honolulu, HI, United States, [2]University of Texas Medical Branch at Galveston, Galveston, TX, United States, [3]Bioqual Inc., Rockville, MD, United States

In 2014 the *Zaire ebolavirus* outbreak in West Africa highlighted the urgent need for an efficacious vaccine. Now, nearly two years after its end, several vaccine candidates are still under preclinical and clinical development. These candidates use a variety of different platforms and the search for markers that correlate with protection is of great interest. Our lab is developing a *Zaire ebolavirus* vaccine based on insect cell expressed recombinant protein subunits. We are currently testing our vaccine in cynomolgus macaques, in which formulations containing the surface glycoprotein (GP) either alone, or in combination with the matrix proteins VP24 and VP40 are protective. Throughout the course of vaccination and challenge, blood samples are collected, and this collection of samples from survivors and nonsurvivors within the same vaccination group gives us a unique opportunity to thoroughly examine immune response differences between animals that are fully protected against Ebola virus disease (EVD) and those that are not. To understand these differences, we have taken PBMCs, stimulated them *ex vivo* with either homologous whole antigen or peptide pools and analyzed cytokine production from their CD4+ and CD8+ T cells and expression of surface activation markers using flow cytometry, ELISpot assays and luminex based multiplex immunoassays (MIA). Collected data have shown that our vaccine candidate primarily elicits a CD4+ T cell response, as indicated by the secretion of cytokines such as IL-4 and TNF-α by these cells upon antigen and peptide pool stimulation. Currently we are extending the analysis of the data collected by these methods after antigenic stimulation of PBMCs from immunized animals to identify differences in the responses between survivors and nonsurvivors to help us define potential correlates of protection.

STANDARDIZATION OF A FOUR-PLEX FORMAT REVERSE TRANSCRIPTION REAL TIME PCR FOR THE SIMULTANEOUS DETECTION OF ZIKA, CHIKUNGUNYA, DENGUE AND YELLOW FEVER IN PERU

Oscar Escalante-Maldonado, Maria Paquita Garcia, Adolfo Marcelo, Cesar Cabezas, Ronnie Gustavo Gavilan

National Institute of Health, Lima, Peru

Mosquitos transmitted diseases have been increasing in the world in the last years. Peru due to its tropical location is one of the most affected areas, where infections by Zika, Chikungunya, Dengue and Yellow Fever viruses are the main problem. Several methods to diagnose these four diseases are currently used in the country such as ELISA, culture and single RT-PCR. However, these methods are time consuming, costly and expensive. A platform that can detect multiple vector-borne viruses at once is required. We put together 15 primers and 7 probes in a single reaction to build a qRT-PCR to detect ZIKV, CHIKV, DENV and YFV simultaneously. We collected 640 serum samples which were previously tested using the RT-PCR (gold standard) individually following the method indicated by the CDC-US. The samples were also tested using the ZCDY RT-PCR multiplex and the sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) were obtained. Cohen's Kappa was determined to measure the concordance between the two methods. Our ZCDY RT-PCR method could detect 282 positives to one of the four etiologies from 640 samples analyzed. These results were also compared with the single RT-PCR routinely used (CDC-US) at the CNSP/INS Peru and it showed a sensitivity of 98.61, a specificity of 99.69, a PPV of 99.80 and a NPV of 97.90. The Cohen's Kappa was 0.980 in a 95% C.I. of 0.966 - 0.994. Based on these results, the ZCDY qRT-PCR method showed to be a powerful molecular tool for rapid, specific and simultaneous detection of etiologies associated with acute febrile syndromes that allows a proper and timely diagnosis of these important infectious diseases.

1664

DEVELOPMENT OF THERMOSTABLE FILOVIRUS VACCINES BASED ON RECOMBINANT INSECT CELL EXPRESSED SUBUNITS

Axel T. Lehrer[1], Teri Ann S. Wong[1], Michael M. Lieberman[1], Liana O. Medina[1], Thomas Geisbert[2]

[1]University of Hawaii, Honolulu, HI, United States, [2]University of Texas Medical Branch, Galveston, TX, United States

Ebola Virus Disease (EVD) is the most prominent example of filovirus disease. Transmission from wild animals into the human population typically causes outbreaks of limited scale in endemic regions, therefore other public health threats usually garner more attention. This changed when the *Zaire Ebolavirus* (EBOV) outbreak in several West African countries claimed more than 11,000 lives and revealed the true epidemic potential that filovirus infections may possess. Despite significant progress with the clinical development of several EBOV vaccine candidates during and after the West African outbreak, no broadly protective vaccines targeting other filoviruses have received regulatory approval. We are developing a trivalent vaccine based on recombinant filovirus glycoproteins (GP) from EBOV, Marburg virus (MARV) and *Sudan ebolavirus* (SUDV) produced using the *Drosophila* S2 cell expression system. The immunogenicity of highly purified recombinant subunits alone or in combinations was evaluated in mice and guinea pigs resulting in strong antigen-specific IgG titers as well as cell mediated immune responses after two or three immunizations. Recombinant vaccine candidates were tested successfully for protection in the mouse and guinea pig models of EBOV and MARV. Studies in two species of non-human primates demonstrate that vaccination with formulations of recombinant EBOV subunits and an emulsion-based adjuvant consistently produces high IgG titers. Vaccination further prevents viremia subsequent to EBOV challenge and protects animals from EVD. Thus we have defined a recombinant subunit EBOV vaccine candidate that forms the basis for further pre-clinical and clinical development of a trivalent filovirus vaccine. Ongoing formulation optimization in our laboratory focuses on thermostabilization of recombinant subunits and adjustment of dosing schedules following promising efficacy testing against EBOV of a single shot recombinant subunit vaccine. These results should enable clinical development of safe and efficacious, field-deployable vaccine candidates for protection against Ebola and Marburg Virus Disease.

1665

SPATIOTEMPORAL HETEROGENEITY IN THE DISTRIBUTION OF CHIKUNGUNYA AND ZIKA VIRUS CASE INCIDENCES AND RISK FACTORS DURING THEIR EPIDEMICS IN BARRANQUILLA (COLOMBIA) BETWEEN 2014 AND 2016

Thomas C. McHale[1], Claudia Romero-Vivas[2], Claudio Fronterre[1], Andrew K. Falconar[2], Naomi Walker[1], Chad Nix[1], Jorge Cano[1]

[1]London School of Hygiene & Tropical Medicine, London, United Kingdom, [2]Universidad del Norte, Barranquilla, Colombia

The chikungunya and Zika viruses have recently emerged as global infections with consequential disability adjusted life years (DALYs) and economic burden. This study aimed to explore the spatiotemporal heterogeneity in the occurrence of chikungunya (CHIKV) and Zika (ZIKV) virus outbreaks in Barranquilla, Colombia during 2014 and 2016 and

to identify socioeconomic, demographic and environmental factors that influenced their distribution. We investigated the spatial distribution of CHIKV and ZIKV incidence across Barranquilla neighbourhoods and explored the potential for clustering. Incidence data were fitted using multiple Bayesian Poisson models based on a suite of explanatory variables as potential risk factors and multiple options for random effects with: i) no random effects, ii) independent random effects, and iii) spatially correlated random effects, implemented through a conditional autoregressive model (CAR). A best-fitted model was used to analyse the case incidence risk for both CHIKV and ZIKV throughout Barranquilla and to identify risk factors during their epidemics. Neighbourhoods in the northern region of Barranquilla, which also houses the highest socioeconomic strata, were hotspots for the outbreaks of CHIKV and ZIKV. Additional hotspots occurred in the southwestern and central regions of the CHIKV and ZIKV outbreaks, respectively. Multivariate CAR models identified strong evidence that higher socioeconomic strata and residing in detached houses were risk factors for ZIKV case incidence. This study provides an evidence-based framework that public health programmes can use to efficiently target specific regions of Barranquilla that are likely to drive future outbreaks of CHIKV and ZIKV infections. Furthermore, we clearly showed that living in high socioeconomic strata was a risk factor for ZIKV case incidence. These novel findings challenge the logic that these infections are driven by social vulnerability—such as low socioeconomic strata, high residential densities, and poor education—and merits further study both in Barranquilla and throughout the tropical and subtropical regions of the world.

1666

TRENDS IN INFLUENZA AND OTHER RESPIRATORY VIRUSES IN SOUTHERN PUERTO RICO, 2012-2017

Gabriela Paz-Bailey[1], Laura Adams[1], Jorge Munoz[1], Mathew Lozier[1], Sonja Olsen[2], Lenee Blanton[2], Steve Waterman[1], Luisa Alvarado[3]

[1]Centers for Disease Control and Prevention, San Juan, PR, United States, [2]Centers for Disease Control and Prevention, Atlanta, GA, United States, [3]Ponce Health Sciences University, Ponce, PR, United States

Influenza seasonality has been described in temperate countries, where influenza activity typically peaks between November and March in the Northern Hemisphere, and between April and September in the Southern Hemisphere. While peaks in influenza activity may be observed in tropical regions, increased surveillance efforts are needed to better define seasonality. We used data from the Sentinel Enhanced Dengue Surveillance System (SEDSS) to describe trends in influenza and other respiratory viruses in southern Puerto Rico during May 2012 to December 2017. Patients presenting to the emergency department at Saint Luke's Episcopal Hospital in Ponce and Guayama, Puerto Rico with onset of fever ≤7 days of presentation were eligible. Nasal swabs were tested for influenza A and B viruses, adenoviruses, respiratory syncytial virus (RSV), coronaviruses, parainfluenza viruses and metapneumovirus by RT-PCR. To identify months with the largest relative frequency of cases in comparison with other times throughout the year, we calculated a monthly case proportion, defined as the number of test-positive cases reported in a given month as a percentage of the total number of cases for each virus reported in the calendar year. We defined a month as having viral activity if the cases represented a fixed threshold of 10% or more of total reported positive cases in the year in two or more years from 2012 through 2017. Among 19,228 participants, 24% were recruited in 2012-2013, 24% in 2014-2015 and 53% in 2016-2017. Overall, 26% of specimens were positive for any respiratory virus: 9% influenza A, 4% influenza B, 4% adenovirus, 4% RSV, and 6% other. In 2012-2013, Influenza A and B viruses occurred year-round showing no clear seasonality. In 2014-2017, influenza activity was identified from December through February. Adenoviruses had increased activity in June through August, and RSV October through December. Understanding the trends in respiratory virus circulation is helpful to target prevention and control strategies, such as vaccination. Current US recommendations are for influenza vaccination before the end of October, which may be appropriate for Puerto Rico.

1667

A RECOMBINANT VESICULAR STOMATITIS VIRUS EXPRESSING THE JUNIN VIRUS GLYCOPROTEIN PROTECTS GUINEA PIGS FROM LETHAL JUNIN VIRUS CHALLENGE

Teresa E. Sorvillo, Daniel J. Deer, Karla A. Fenton, Joan B. Geisbert, Chad E. Mire, Thomas W. Geisbert

University of Texas Medical Branch, Galveston, TX, United States

Junin virus (JUNV) is a highly virulent arenavirus and the causative agent of Argentine hemorrhagic fever (AHF). It is considered a significant biodefense concern and NIAID category A pathogen due to its potential for aerosol transmission and mortality rates upwards of 30%. Currently, a single live-attenuated vaccine (Candid #1) is available for prevention of AHF in Argentina, however, this vaccine has a number of significant limitations which preclude it from receiving Food and Drug Administration (FDA) approval in the United States. Specifically, Candid #1 retains a low level of neurotropism and has an instable attenuated phenotype, with a single in-vivo passage yielding isolates up to 100-fold more virulent. In this study, we look at developing a vaccine alternative which overcomes these limitations and has promise for FDA licensure as a biodefense vaccine. Vesicular stomatitis virus (VSV) based vaccines against hemorrhagic fever viruses have shown promise as demonstrated by a recent successful Phase III clinical trial against Ebola virus in Guinea. VSV infection is typically asymptomatic or causes mild disease in humans and has low seroprevalence in human populations making it an ideal vaccine platform. In this study, a recombinant VSV expressing the JUNV surface glycoprotein (rVSVΔG-JUNVGP) was cloned, recovered, and characterized. Two groups of 6 guinea pigs each received a prime dose of rVSVΔG-JUNVGP thirty-five days before lethal JUNV challenge. One group received a boost dose fourteen days before challenge. Survival for animals receiving the prime versus prime-boost injection was 17% and 83%, respectively. Importantly, none of the surviving animals had detectable viremia at days 7, 14, or 35. No evidence of JUNV was found in the tissues of survivors including the liver, spleen, or brain at the study end. Additionally, no significant lesions or viral antigen was observed in the liver, spleen, or brain of surviving animals via histology.

1668

DIAGNOSTIC NEEDS FOR LASSA FEVER OUTBREAK DETECTION, CLINICAL CARE, AND VACCINE DEVELOPMENT

Devy M. Emperador[1], Solomon A. Yimer[2], Laura T. Mazzola[1], Cassandra Kelly-Cirino[1]

[1]Foundation for Innovative New Diagnostics, Geneva, Switzerland, [2]Coalition for Epidemic Preparedness Innovations, Oslo, Norway

Lassa fever, caused by arenavirus Lassa virus (LASV), is an acute viral hemorrhagic disease that affects up to 300,000 individuals and causes up to 5,000 deaths per year in Western Africa. There are at least 4 geographically distinct lineages of LASV circulating in the region. Early detection of LASV infection is difficult as the clinical course can range from 2-21 days, with 80% of those infected having asymptomatic or mild disease, and the majority of patients presenting at a health center already progressed to severe stage. Currently available LASV diagnostic methods are difficult to operationalize in low resource health centers and may be less sensitive to detecting all known or emerging LASV strains. To understand and prioritize the diagnostic gaps, we conducted a landscape and developed use cases for: 1) diagnostics for outbreak and non-outbreak clinical care in low resource hospitals and clinics, and 2) diagnostic support for surveillance and vaccine development in LASV-affected countries. In general, there is a lack of fully validated and regulated commercial assays for LASV, with many of the tests unable to detect all LASV lineages (pan-LASV). For outbreak response, diagnostics are needed for point-of-care (POC) and near-patient testing that enable pan-LASV pathogen detection as well as differentiation from other endemic causes of fever. POC and near-patient nucleic acid tests (NATs) are critical for rapid diagnosis, with a secondary role of immunoassays (IAs) for community triage; these tests

are also important for non-outbreak clinical care. For surveillance and vaccine development, pan-LASV detection is important for understanding LASV incidence and prevalence, especially for vaccine clinical trials. The 2017-2018 Lassa outbreak in Nigeria has clearly identified diagnostics needed for: 1) POC and near-patient NATs for rapid detection of pan-LASV and differentiation from other fever-causing pathogens, 2) improved IAs to support surveillance and vaccine development, and 3) POC IAs for community-based screening and triage.

1669

ISOLATION OF CHIKUNGUNYA VIRUS FROM HUMANS IN CHIAPAS, MEXICO

Pedro M. Palermo[1], Ana L. Gonzalez-Perez[2], Jose G. Estrada-Franco[3], Douglas M. Watts[1]

[1]University of Texas at El Paso, El Paso, TX, United States, [2]Universidad Autonoma del Estado de Mexico, Toluca, Mexico, [3]Centro de Biotecnologia Genomica, Reynosa, Mexico

Chikungunya virus (CHIKV) is an emerging arthropod-borne virus introduced into the Americas in 2013. CHIKV is transmitted to humans by *Aedes aegypti* and *Ae. albopictus* mosquitoes, causing fever and severe arthralgia. In Mexico, human cases of CHIKV have been reported since 2014. However, part of CHIKV outbreaks has not been described due to the lack of diagnostic assays. An outbreak of acute undifferentiated fever occurred from July to August 2015 in two localities in the central valley region of Chiapas, Mexico. Seventy-four human sera samples were collected from patients experienced fever, arthralgia, and headache. Sera samples were tested by cell culture on C6/36 cells and immunofluorescence assays. Seventeen out of seventy-four samples (22.9%) reacted against only CHIKV antibody and RNA extracted from the cell supernatants was positive for a generic reverse transcription polymerase chain reaction (RT-PCR) for Alphaviruses, and further identified as CHIKV by sequencing. Analysis of the envelope-1 gene clustered the CHIKV isolates in the Asian lineage. This study reports by the first time the presence of CHIKV in the central valley of Chiapas, Mexico.

1670

GENOMIC EPIDEMIOLOGY OF RABIES VIRUS IN THE EASTERN UNITED STATES

Nathan L. Yozwiak[1], Sarah M. Winnicki[1], Timelia Fink[2], Anne Piantadosi[1], Scott Hennigan[2], Tiffany Hsu[2], Christopher Tomkins-Tinch[1], Glen R. Gallagher[2], Catherine Brown[2], Daniel J. Park[1], Sandra Smole[2], Pardis C. Sabeti[1]

[1]Broad Institute, Cambridge, MA, United States, [2]Massachusetts Department of Health, Boston, MA, United States

Rabies virus (RABV) remains enzootic in the United States in wild mammals, with distinct variants in raccoons, skunks, foxes, and bats. Passive surveillance of RABV is conducted largely by state laboratories and seeks to monitor and mitigate rabies spillover into humans, domestic animals, and new host species. RABV variant information is used to monitor regional transmission dynamics and shifts to new hosts, and informs treatment management for animal exposures, but variant typing or full genome sequencing is not regularly performed. We will describe current rabies virus diversity, and introduce a new training partnership between MA DPH and the Broad to enhance laboratory sequencing capabilities, using rabies as a training set. Over twenty participants from seven state labs attended the training workshops in 2017-18 and generated over 80 new RABV genomes collected from eight mammal species. These sequences reveal new RABV subclades structured by region as well as individual but unsustained cross-species transmission. Expanded laboratory sequencing in state public health labs open new opportunities to establish coordinated networks for genomic surveillance, with immediate application for rabies monitoring in the U.S.

1671

ISOLATION OF BACTERIOPHAGES FROM THE PERUVIAN AMAZON RIVER BASIN AGAINST CLINICALLY RELEVANT MULTI-DRUG RESISTANT (MDR) *KLEBSIELLA PNEUMONIA* IN SUPPORT OF PHAGE THERAPEUTIC DEVELOPMENT

Jose Chu Luo[1], Gillian R. Naro[1], Ricardo Abadie[2], Patrick Schukraft[1], Rutu Dave[1], Robert Fort[1], David Craft[1], James Regeimbal[2]

[1]Pennsylvania State University College of Medicine, Hershey, PA, United States, [2]Naval Medical Research Unit No. 6, Lima, Peru

Bacteriophages kill bacteria in a specific manner and were recently used in the successful treatment of a moribund patient suffering from a systemic MDR *A. baumannii* infection in the U.S., using personalized cocktails via a library-to-cocktail approach. The continued advancement of phage therapeutics is dependent on the expansion of diverse lytic phage libraries against clinically relevant bacteria. Here we harvested phages from the Amazonian River Basin in Iquitos, Peru, using local MDR *K. pneumoniae* (KP) clinical isolates, and interrogated their host-ranges against a larger panel of MDR KP clinical strains. 10 clinical MDR KP strains with different resistance profiles; isolated from hospitals in Iquitos from 2011 to 2017, were used to isolate phages from local sewage. Phage-rich water (300 ml) from a sewage canal was mixed with 3% w/v TSB-powder, inoculated with 5 different exponential MDR KP strains, and grown overnight at 37°C shaking. Two such cultures were generated totaling 10 MDR KP strains used for phage isolation. Centrifuged supernatants were sterile filtered and serial dilutions spotted onto individual lawns of the 5 MDR KP isolates and incubated at 37°C overnight. Agar plugs of well isolated plaques were re-suspended in PBS and filter sterilized. Preliminary host-ranges were defined using similar spot-plates with the 10 original host MDR KP strains, and an additional 10 MDR KP isolates. 10 total KP phages were isolated using the two phage harvesting cultures. These phages covered 8 of the 20 total MDR KP strains. 8 of the 10 phages only infected the host strain on which each was isolated. 2 of the 10 phages showed broader activity: KP07ϕ1 formed plaques on 7 of the 20 MDR KP strains, and KP07ϕ2 formed plaques on 3. In this study we readily isolated both "narrow" and "broad" host-range phages against MDR KP clinical isolates from a remote source. Isolating diverse phages with unique host ranges is critical for the development of a robust phage library capable of supporting personalized therapeutic cocktails. Our initial results justify ongoing expansion of geographically broad and diverse phage libraries against MDR bacterial pathogens.

CYTOMEGALOVIRUS-RELATED CHANGES IN T CELL PHENOTYPE ARE ASSOCIATED WITH REDUCED VACCINE RESPONSES IN YOUNG ADULTS IN THE UK AND SENEGAL

Georgina Bowyer[1], Navin Venkatraman[1], Pierre Birahim Ndiaye[2], Djibril Wade[2], Nicole Brenner[3], Momar Bakhoum[2], Catherine Mair[1], Tim Waterboer[3], Tandakha Dieye[2], Souleymane Mboup[2], Adrian VS Hill[1], Katie Ewer[1]

[1]University of Oxford, Oxford, United Kingdom, [2]Centre Hospitalier Universitaire le Dantec, Dakar, Senegal, [3]German Cancer Research Center, Heidelberg, Germany

During concurrent Phase I clinical trials of viral-vectored Ebola vaccine candidates in healthy young adults (aged 18-50 years) in the UK (n=16) and Senegal (n=40), we observed significantly reduced humoral responses in Senegalese vaccinees compared with the UK cohort. Although often noted that vaccine responses are reduced in developing countries, there are very few studies that investigate the potential mechanisms underlying this phenomenon. A higher pathogen burden, particularly with chronically infecting pathogens, may be a factor associated with dysregulated or suppressed immune responses. Volunteers were vaccinated with a chimpanzee adenovirus expressing Zaire Ebola glycoprotein (ChAd3-

EBO Z) and boosted one week later with modified vaccinia virus Ankara, also expressing Zaire Ebola glycoprotein (MVA-EBO Z). Using a multiplex assay, we assessed the serostatus of individuals in each cohort for 18 different pathogens that cause chronic, latent or repeated infections. All of the Senegalese and 50% of the UK cohort were positive for CMV IgG. CMV seropositivity was associated with significant diferences in the global T cell repertoire with a shift towards late-differentiated memory T cells expressing CD57 and killer cell lectin-like receptor G1 (KLRG1). In CMV+ individuals in the UK $CD57^{+}KLRG1^{+}$ cells formed 2.5% of the total $CD4^{+}$ subset and 16.9% of the total $CD8^{+}$ subset compared to just 0.06% of $CD4^{+}$ T cells and 4.0% of $CD8^{+}$ T cells in CMV- individuals. T cell repertoires in Senegalese individuals were comparable to UK CMV+ individuals. The proportion of $CD57^{+}KLRG1^{+}$ $CD4^{+}$ T cells was associated with CMV IgG titres in both cohorts. These populations were not associated with any other pathogen tested and negatively correlated with vaccine responses in both cohorts. This study suggests that CMV, which has previously been associated with immunosenescence and reduced vaccine immunogenicity in elderly populations, can impact vaccine responses in young adults and may have a particularly marked impact in developing countries where CMV seropositivity is almost universal.

1673

A GLOBAL SUCCESS STORY: THE INCREDIBLE DECLINE OF POLIOMYELITIS INCIDENCE, PREVALENCE, AND MORTALITY. RESULTS FROM THE GLOBAL BURDEN OF DISEASE STUDY 2017

Christopher Troeger, Ibrahim Khalil, Brigette Blacker, Samuel Albertson, Robert Reiner

Institute for Health Metrics and Evaluation, Seattle, WA, United States

Wild poliovirus continues to circulate in only three countries globally, representing an enormous decrease in its burden due to a global effort to eradicate the disease. The Global Burden of Diseases, Injuries, and Risk Factors Study 2017 (GBD 2017) is a systematic, scientific effort to measure health loss globally and reintroduced poliomyelitis as a cause of death and disability. We estimated the historical incidence and mortality due to poliovirus from 1980 to 2017 including the lifelong prevalence of paralysis and disability. Acute paralysis due to poliovirus incidence was modeled using notification and surveillance data. We used a cohort model to track the prevalence of acute and permanent paralysis due to poliomyelitis as well as of post-polio syndrome for every geography, both sexes, and all ages. We estimated 4,430,000 prevalent cases of paralytic polio in 1990 (95% Uncertainty Interval [UI] 3,022,000-5,899,000). We estimated that there was a 99% decline in poliomyelitis incidence between 1980 and 2017. Based on a meta-analysis of the case fatality ratio of acute poliomyelitis, we estimated that there were 5,020 (95% UI 3,300-7,300) deaths due to poliomyelitis in 1990. Lifelong disability due to poliomyelitis represents a significant burden of disease, accounting for 1,611,000 years lived with disability (YLDs) in 1990 (95% UI 980,000-2,372,000) and 962,000 YLDs in 2017 (95% UI 589,000-1,394,000). Global eradication of wild poliovirus may be within reach and will represent an enormous public health achievement, particularly when viewing its significant historical burden.

1674

FRUIT BAT ECTOPARASITES OF BUNDIBUGYO DISTRICT, UGANDA HOST DIVERSE RHABDOVIRUSES: IMPLICATIONS FOR VECTORBORNE TRANSMISSION OF "BAT-ASSOCIATED" VIRUSES

Andrew J. Bennett, Jess Carag, Tony L. Goldberg

University of Wisconsin Madison, Madison, WI, United States

Bats are the natural reservoir for diverse, highly virulent emerging (-) ssRNA viral pathogens such as Rabies virus, Marburg virus, and Nipah virus. The role that ectoparasites play in the transmission and maintenance of bat viruses is poorly understood, but the recent discovery of a bat fly rhabdovirus related to "bat-associated" viruses of the Ledantevirus genus suggests that ectoparasites may play a role. The relationship of Kanyawara virus to the eponymous Le Dantec virus, first isolated in Senegal from the serum of a patient with fever and hepatospenomegaly, suggests that further research into the diversity of Ledanteviruses is warranted. As part of a study of the ecology of emerging bat viruses in Bundibugyo District, Uganda we collected Nycteribiid bat flies - highly specialized hematophagous dipterans - from Myonycteris sp. fruit bats. We used next-generation sequencing to explore the diversity of bat fly rhabdoviruses in an emerging infectious disease hot spot. We identified diverse viruses that dramatically expand the known diversity of bat fly rhabdoviruses, and provide insight into the relationship between bat ectoparasite rhabdoviruses and "bat-associated" viruses.

1675

DETERMINING THE EFFICACY, SAFETY, AND SUITABILITY OF DISINFECTANTS TO PREVENT EMERGING INFECTIOUS DISEASE TRANSMISSION

Daniele S. Lantagne[1], Marlene Wolfe[1], Karin Gallandat[1], Melissa Opryszko[2]

[1]Tufts University, Medford, MA, United States, [2]OFDA, Washington, DC, United States

The scale of the 2014-2017 West African Ebola Virus Disease outbreak overwhelmed international response capacity. This led to inconsistencies in international guidance documents, particularly around chlorine disinfection of surfaces and hands to prevent ongoing transmission, which lacked a basis in evidence. To provide the necessary evidence-base for international disinfection recommendations, which in general recommend the use of 0.5% chlorine solution to disinfect non-living things (e.g. surfaces, dead bodies) and 0.05% solution to disinfect living things (e.g. hands), three research strands were conducted: 1) impacts of source chlorine chemistry of the four chlorine compounds used in Ebola contexts (HTH, NaDCC, NaOCl, gNaOCl); 2) efficacy of surface cleaning recommendations on stainless steel, nitrile, and heavy duty tarp surfaces using the Ebola surrogate bacteriophage Phi6; and, 3) safety and efficacy of the recommendation to use 0.05% chlorine solutions for community handwashing, also using Phi6 on hands. Strand 1 research found source chlorine compound chemistry impacts chlorine solution shelf-life (4 hours-30 days) and testing of chlorine solutions with one reliable test strip or portable iodimetric titration is recommended to ensure solution accuracy. Strand 2 research found surface cleaning with 0.5% chlorine solutions with a 15-minute exposure time is efficacious at reducing transmission risk across all surface types tested. Strand 3 research found community handwashing with chlorine solutions is as safe and efficacious as handwashing with soap and water or sanitizer, and offers a benefit of reducing pathogens in rinse water stored in buckets. Across all studies, the source chlorine compound calcium hypochlorite performed particularly well. The research was successful at providing information to align inconsistent international guidelines. Further research is needed to proactively establish the efficacy, safety, and suitability of disinfectants and sterilizers for the seven viral pathogens considered likely to cause severe outbreaks with few/no medical countermeasures.

MAPPING ROTAVIRUS DIARRHEA IN CHILDREN AT THE 5 X 5 KM SCALE ACROSS AFRICA, 2000 - 2016

Aniruddha Deshpande, Brigette F. Blacker, Daniel C. Casey, Christopher Troeger, Mathew M. Baumann, Simon I. Hay, Robert C. Reiner Jr.

Institute for Health Metrics and Evaluation, Seattle, WA, United States

Rotavirus is a ubiquitous diarrheal pathogen and is the leading cause of diarrhea mortality across the African continent. The 2016 GBD Study estimates that rotavirus was responsible for approximately 129,000

deaths in sub-Saharan Africa among children under 5 years old in 2016. By integrating a Bayesian geostatistical mapping effort powered by over 191 household-level surveys with the 2016 GBD Study, we have created, for the first time, high-resolution (5x5km) estimates of the prevalence, incidence, and mortality associated with rotavirus across the African continent from 2000-2016. Diarrhea mortality has decreased over the past 16 years for a number of reasons, and countries that have introduced the rotavirus vaccine have seen additional decline. However, health gains have not been equitably distributed between within countries. For example, the rotavirus mortality rate decreased by over 85% in several first administrative subdivisions in Angola from 2000 to 2016, whereas countries such as Swaziland saw a limited decrease in burden during that time period. Moreover, our results highlight inequalities within countries. For example, Nigeria observed the largest within country variation, with mortality rates nearly six times greater in the country's north eastern region compared the southern coast. The continued reduction of rotavirus diarrhea burden in Africa hinges upon addressing local inequalities by directing resources to the areas where the largest gaps remain. Estimates at such a granular scale are imperative for accurately targeting interventions and policies in areas that may otherwise be masked by maps that aggregate to the country or first administrative subdivision level.

ASSOCIATION OF ADENOVIRUSES 40-41 AND AICHIVIRUS TO DIARRHEA IN MEDICALLY-ATTENDED CHILDREN IN PERU

Holger Mayta[1], Alejandra A. Ingunza[1], Mayra R. Ochoa[1], Karen Neira-Cruzado[1], Gerardo Sánchez[1], Macarena Vittet[1], Mishel Sandoval[1], Monica Pajuelo[1], Fabiola Colquechagua[1], Lilia Cabrera[2], Dante A. Figueroa-Quintanilla[3], Mayuko Saito[4], Sarah-Blythe Ballard[5], Robert H. Gilman[5]

[1]Infectious Diseases Research Laboratory, Department of Cellular and Molecular Sciences, Universidad Peruana Cayetano Heredia, Lima, Peru, [2]Asociación Benéfica PRISMA, Lima, Peru, [3]Unidad de Rehidratación Oral, Instituto Nacional del Salud del Niño, Lima, Peru, [4]Department of Virology, Tohoku University Graduate School of Medicine, Sendai, Japan, [5]Department of International Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States

Diarrheal disease is still a leading cause of mortality among children under five. The disease is caused by a variety of agents including bacteria, parasites, and virus; but frequently no etiological agent is identified, suggesting that other viral agents may be involved. Adenovirus and aichivirus has been reported as etiology of diarrhea but its attribution to the diarrhea in children is limited. A case-control study was conducted to evaluate the association of human adenovirus 40-41, and aichivirus with acute gastroenteritis in children younger than five years of age seeking for medical attention at the national children's hospital in Peru following universal Rotarix™ vaccine implementation. Stool samples were analyzed using qPCR. Positive samples were tested for adenovirus 40-41 by conventional PCR while aichivirus positive samples were amplified by conventional PCR and sequenced. Human adenovirus 40 was present in 2.44% (4/164) of cases and 0.61% (1/164) of controls, while Adenovirus 41 was present only among cases (6.71%, 11/164). The OR for adenovirus 40-41 was 16.41 (95% CI: 2.145-36.86). Aichivirus was present in 2.44% (4/164) of cases and in 1.23 (2/164) of controls (OR=2.03, 95% CI:0.37-11.21); however, all aichivirus qPCR positive samples were negative by conventional PCR. Human adenoviruses 40-41 are an important cause of diarrhea among children with medically-attended diarrhea in Peru.

1678

ISOLATION, SUBTYPE DETERMINATION AND ALTENUATION OF LASSA FEVER VIRUS FROM WILD RODENTS IN SOUTHWEST NIGERIA

Oyewale A. Oyediran

University of Ibadan, Ibadan, Nigeria

The project is focused on vector ecology and virus epidemiology, skills in studying emerging viruses Molecular characterization of isolates from a wider geographic area to fully understand the diversity of the LASV strains and its impact on disease distribution and risks. Such information would be useful for developing efficient viral detection technologies, for example, enabling design of PCR primers and antibodies specific for a broad range of LASV types. These diagnostic tests are extremely relevant to disease surveillance, monitoring and evaluation of interventions to prevent primary LASV epidemics in humans. More extensive information about sequence diversity affecting the antigenicity of the virus or the function of its RNA-dependent, RNA polymerase may help in the development of vaccines and antiviral drugs. It will also lead to deeper understanding of the biology and pathogenesis of LASV Reconcile age-related surveillance trends through an immune-epidemiologic hypothesis, age-related patterns in cross-reactive strains humoral and cell-mediated immunity that may correlate with outcomes.determine presence of homologous and cross-negative neuraminidase-inhibiting(NI) antibodies against viral strains in sera. Results from this study will add to the current, the existing body of knowledge about Lassa Hemorrhagic fever. Further investigations may open potential therapy/vaccine candidates. The study is relevant to public health policy and practice in combination therapy approach to enhance immunity towards prevention, treatment and control of Lassa fever infection.

7-HYDROXYSTAUROSPORINE, UCN-01, IS AN EFFECTIVE INHIBITOR OF LIPID ENVELOPED VIRUS REPLICATION

Mark Fraser[1], Arwa Mohammad[1], Scott Olehnik[1], Jennifer Brannan[2], Robert Stahelin[3]

[1]University of Notre Dame, Notre Dame, IN, United States, [2]United States Army Medical Research Institute of Infectious Diseases, Frederick, MD, United States, [3]Purdue University, West Lafayette, IN, United States

Apoptotic mimicry utilized by lipid-enveloped viruses for infection is dependent on external leaflet viral phosphatidylserine (PS) expression and host cell kinase activity involving TIM proteins, AXL, and TYRO3. In addition, it has been shown that matrix proteins Ebola VP40 and HIV-1-Gag induce external leaflet expression of PS. UCN-01 is a staurosporine FDA approved for phase II clinical trials for multiple neoplasms, which acts as a non-specific kinase inhibitor and has been shown to disrupt PS localization to the plasma membrane by redistributing to endomembranes. By utilizing UCN-01 at lower concentrations than used for anti-cancer clinical trials it is hypothesized that viral replication in multiple lipid enveloped viruses can be inhibited in two ways: first, by inhibiting matrix protein localization to the plasma membrane and viral budding by localizing PS to endomembranes from the plasma membrane, and second, by inhibiting viral infection which utilizes apoptotic mimicry by reducing available PS on viral particles and by also inhibiting host cell kinase activity of receptor proteins known to interact with PS. Cellular toxicity of UCN-01 was reproduced from the literature and concentrations from 50-400nM were determined to be within the acceptable range in the cells being studied. Using these concentrations UCN-01 was shown to reduce plasma membrane localization of Ebola VP40 and HIV-1-Gag significantly using confocal imaging of recombinant GFP tagged viral proteins. Changes in budding were then assessed in Marburg VP40 and Ebola VP40 using western blot with significant increases in budding at 200nM and 300nM in Ebola VP40. Live Chikungunya virus and Ebola virus was shown to be inhibited by UCN-01 treatment. TEM and SEM of Ebola VP40 and Marburg VP40 producing cells treated with UCN-01 will be performed in addition to localization assays utilizing fluorescent probes for Ebola VP40, Marburg

VP40, and HIV-1-gag. UCN-01 inhibition on kinase activity of AXL and TYRO3 will also be performed in-vitro. Finally, live virus studies will be expanded to include Dengue virus, HIV-1, a second Ebola virus strain, Marburg virus, and Zika virus.

ATORVASTATIN REDUCES MALARIA LIVER STAGE DEVELOPMENT IN A RODENT MODEL

Marijke Langenberg[1], Lisa Hoving[1], Séverine Chevalley-Maurel[1], Amanda Pronk[1], Carola Feijt[1], Beatrice Winkel[1], Chris Janse[1], Hans Princen[2], Vanessa van Harmelen[1], Ko Willems van Dijk[1], Blandine Franke-Fayard[1], Meta Roestenberg[1]

[1]LUMC, Leiden, Netherlands, [2]TNO, Leiden, Netherlands

Malaria parasites use a complex metabolic machinery to grow inside host cells such as red blood cells and hepatocytes, but lack the enzymes to synthesize the sterols they need for multiplication inside these cells. Within a hepatocyte a single parasite produces >10.000 daughter parasites, representing one of the fastest multiplication rates among eukaryotic cells. To meet the metabolic demand for this rapid proliferation, the parasite scavenge sterols from its host cell. Given the world-wide exponential increase in metabolic diseases, and the concomitant use of lipid lowering drugs, we used the *Plasmodium berghei* rodent malaria model to investigate the effects of such metabolic drugs on parasite multiplication in the liver. C57BL/6 mice were treated with atorvastatin (AT), atorvastatin in combination with ezetimibe (AT+EZ) or alirocumab (AL) for three weeks after which they were infected with either sporozoites or blood stages of a transgenic *P. berghei* parasite expressing luciferase. Treatment with AT or with AT+EZ altered the lipid metabolism of mice, resulting in weight loss, a reduction in plasma cholesterol and plasma triglycerides levels and reduced liver cholesterol content. However, treatment with AL did not result in an reduction of liver lipid content despite reduced plasma cholesterol levels. A lower liver lipid content paralleled reduced parasite liver loads as measured by *in vivo* imaging of luciferase expressing parasites. Mice treated with AT+EZ had impaired parasite development in the liver resulting in 55% and 86% reduction in blood stage infection, monitored with blood smears, compared to control mice. As expected, the mice treated with AL did not reveal significant differences in parasite liver loads despite the reduced levels of plasma lipids. AT and AL did not affect blood stage parasite multiplication. In conclusion, treatment with commonly used lipid-lowering medication such as atorvastatin with or without ezetimibe significantly reduced parasite liver loads. This study provides a proof-of-principle for how manipulations in the host metabolism can affect the replication potential of malaria parasites.

CASE OF SYMPTOMATIC *PLASMODIUM VIVAX* INFECTION WITH PARASITE DENSITY HIGHER THAN COMMONLY OBSERVED IN DUFFY BLOOD GROUP NEGATIVE PATIENT IN MALI, WEST AFRICA

Amadou Niangaly[1], Tamarah Koleala[2], Safiatou Niare[1], Leonie Raijmakers[2], Abdoulaye K. Kone[1], Boubacar Niare[1], Ivo Mueller[2], Mahamadou A. Thera[1], Ogobara K. Doumbo[1]

[1]Malaria Research and Training Center, Bamako, Mali, [2]Walter and Eliza Hall Institute for Medical Research, Parkville, Australia

Plasmodium vivax was assumed not to be able to infect the red blood cells of Duffy blood group negative people particularly in Central and West Africa. In the last decade, *P. vivax* has been observed across Africa, including in areas inhabited predominantly by Duffy-negative populations. Previous studies suggested that *P. vivax* invasion and reproduction are less efficient in Duffy blood group negative people, with very low parasite densities reported. Subsequently infection is generally milder than that observed in Duffy-positive individuals. Even so, our recent data have shown that chronic carriage of asymptomatic *P. vivax* infection in Duffy-negative individuals can be associated with anemia. In addition we report a case of *P. vivax* infection in a febrile Duffy blood group negative individual with high parasite density. Blood samples were collected during outpatient examination in health centres during malaria transmission season in northern Mali, West Africa. Quantitative PCR was used to detect *Plasmodium* species and quantification. A PCR RFLP using Styl and Banl endonuclease digestion was performed to determine Duffy blood group phenotype. Of 1320 individuals sampled, 316 detected *P. falciparum* infections. Two febrile cases of *P. vivax* mono-infection occurred in a 29-year-old Duffy-positive male with parasite density of 126 parasites/uL and in an 11-year-old Duffy-negative male with parasite density of 4670 parasite/uL. Our data indicates that *P. vivax* density could be higher than generally assumed in Duffy-blood-group negative patients in sub-Sahara Africa.

1682

EXPLORATION OF CROSSTALK BETWEEN INFLAMMATION, COAGULATION, AND OXIDATIVE STRESS HOST RESPONSES IN MALARIA-INDUCED MIDGESTATIONAL PREGNANCY LOSS IN A RODENT MODEL

Alicer K. Andrew, Demba Sarr, Tara C. Bracken, Sachi Shastri, **Julie M. Moore**

University of Georgia, Athens, GA, United States

Placental malaria (PM) is a major complication of *Plasmodium falciparum* malaria that impacts hundreds of thousands of pregnancies annually, contributing to pregnancy loss, preterm delivery, and infant low birth weight. Mouse models for malaria infection during pregnancy have been instrumental in our current understanding of PM, but this understanding remains incomplete. We have developed a mouse model of infection during pregnancy using the murine-infective species P. chaubaudi chaubaudi AS. Infection initiated at gestation day 0 in mice deficient in either tumor necrosis factor or tissue factor function and intact C57BL/6J control mice treated with antioxidant and anticoagulant drugs were used to probe host responses to malaria infection during pregnancy. While unmanipulated control mice lose their pregnancies, tumor necrosis factor- and tissue factor-deficient and drug-treated mice experience improved embryo viability at mid-gestation. These findings suggest that by disrupting the function of key host mediators of severe malaria, it may be possible to mitigate negative pregnancy outcomes associated with malaria. Through strategic use of genetically modified mice, combined with studies of gene expression, tissue staining, and therapeutic intervention, this work investigates the crosstalk between three major host responses to infection - inflammation, coagulation and oxidative stress - and characterizes how their interplay may contribute to PM pathogenesis and associated poor pregnancy outcomes.

1683

ZINC AND OTHER METAL CONCENTRATIONS IN UGANDAN CHILDREN WITH SEVERE MALARIAL ANEMIA COMPARED TO COMMUNITY CHILDREN

Dibyadyuti Datta[1], Robert O. Wright[2], Robert O. Opoka[3], Matthew J. Mazzella[2], Chris Gennings[2], Chandy C. John[1]

[1]Ryan White Center for Pediatric Infectious Disease and Global Health, Department of Pediatrics, Indiana University School of Medicine, Indianapolis, IN, United States, [2]Department of Environmental Medicine, Icahn School of Medicine at Mount Sinai, New York City, NY, United States, [3]Department of Paediatrics and Child Health, Makerere University, Kampala, Uganda

Metals, including zinc and copper among others, can affect immune function and physiologic processes in children, and may predispose to infection or to increased disease severity. To investigate how metal levels may affect risk of severe malaria, we measured the concentrations of 17 metals in whole blood in Ugandan children with severe malarial anemia (SMA, n=199) and compared results to age-matched, healthy community

children without acute illness (CC, n=21), using inductively coupled mass spectrometry. Concentrations were compared between SMA and CC, adjusted for age, sex, socioeconomic status and nutrition. The data were randomly split between a training set (40%) and a validation set (60%). Two WQS indices of deciled-scored concentrations were estimated for the study group comparisons using generalized weighted quantile sum (WQS) regression with a logit link. The resulting WQS index in children with SMA compared to CC showed a mixture effect with significantly higher levels of tin, copper, and manganese and significantly lower levels of selenium, zinc, molybdenum, magnesium, cadmium and cobalt (P values for both mixtures <0.0001 in the validation data set). Results suggest that SMA dysregulates multiple biologically active metals which could play a role in acute and chronic SMA related morbidities. Future studies will investigate the associations of these metal concentrations with inflammatory markers and with measures of acute and chronic morbidity in these children, such as neurodevelopment.

EXTRACELLULAR FLUX ANALYSIS REVEALS THE MAJOR METABOLIC SHIFT AND DIFFERENTIAL SUBSTRATE UTILIZATION FOR OXPHOS ACTIVITY DURING GAMETOCYTE DEVELOPMENT

Tomoyo Kato, Dyann F. Wirth

Harvard T.H. Chan School of Public Health, Boston, MA, United States

The causative agent of malaria, *Plasmodium falciparum*, has a complicated life cycle consisting of multiple developmental stages in the human host and the mosquito vector. Earlier reports have indicated that blood-stage parasites in the human host rely on glycolysis as their primary energy source, while mosquito stages fully depend on mitochondrial oxidative phosphorylation (OXPHOS). These observations suggest that malaria parasites achieve a huge metabolic shift from human to mosquito stages, but raise the question of when and how this shift occurs. Previously, we developed a robust bioenergetic assay for blood-stage parasites utilizing an Extracellular Flux Analyzer. It enables simultaneous investigation of mitochondrial respiration and glycolysis in a physiologically relevant microenvironment with readouts of an oxygen consumption rate (OCR) and extracellular acidification rate (ECAR). With this assay system we demonstrated a robust glycolytic but an inefficient OXPHOS activities in schizonts (late asexual stage). We now report a dramatic increase of OXPHOS over the course of gametocytes development (sexual stage). We investigated differential substrate utilization for OXPHOS at various developmental stages in gametocytes. Among six tested substrates [glycerol-3-phosphate (G3P), dihydroorotate, glutamate, malate, succinate and pyruvate], we found that G3P gave the highest OCR increase in early stage gametocytes (day 6 and 8) similar to schizonts. Responses to both G3P and malate decreased over the course of development and we observed that pyruvate increased the OCR in late stage gametocytes (day 10 and 12). In contrast, pyruvate had no effect on OCR in schizonts. These results suggest that parasites significantly change their metabolic pathways to achieve more efficient ATP production by OXPHOS in order to support successful transmission to mosquitoes. Further details of substrate utilization as well as fatty acid ß-oxidation will be discussed. Our findings may suggest the mitochondrion OXPHOS pathway as a unique target for transmission blocking therapeutics.

1685

DISSECTING THE MECHANISMS OF MALARIA INDUCED ANEMIA IN RODENT MALARIA MODELS

Keyla C. Tumas, Jian Wu, Lu Xia, Timothy G. Myers, Xin-zhuan Su

National Institutes of Health, Bethesda, MD, United States

Malaria induced severe anemia is likely multifactorial, arising from clearance of infected and uninfected red blood cells and an inhibition in erythropoiesis, the production of new red blood cells. However, the exact molecular mechanisms contributing to both red blood cell clearance and inhibition of erythropoiesis are still widely unknown. Using *Plasmodium yoelii* parasites N67C strain and 17XNL strain, we are dissecting the molecular mechanisms of malaria induced anemia. From microarray analysis, the N67C strain has decreased expression of erythropoietic associated genes at day 4 post infection. In contrast, the 17XNL strain has an initial inhibition of erythroid associated genes but later in the infection shows an increase in expression. Therefore, using these two rodent models, we aim to further measure and characterize the effect of malaria infections on erythropoiesis in the host. Using flow cytometry analysis of the bone marrow and spleen, we found differences of cell populations of progenitor cells and late stage cells of hematopoiesis and erythropoiesis when comparing infected mice to non-infected mice. In particular, the N67C strain had decreased cell frequencies for proerythroblast and other early cell stages of erythropoiesis on day 4 post infection. Our aims are to elucidate the molecular mechanisms contributing to the changes in hematopoiesis and to advance our understanding of malaria induced anemia.

1686

AN ER-RESIDENT HSP40 IS REQUIRED FOR THE ASEXUAL DEVELOPMENT OF THE MALARIA PARASITE *PLASMODIUM FALCIPARUM*

David W. Cobb, Heather M. Kudyba, Baylee Bruton, Vasant Muralidharan

University of Georgia, Athens, GA, United States

Malaria remains a significant global health burden. The parasitic disease kills hundreds of millions of people every year, with infection by *Plasmodium falciparum* associated with the most severe cases of malaria. All of the clinical symptoms of malaria result from the asexual replication of *Plasmodium* parasites within human red blood cells (RBCs); thus, an understanding of the mechanisms used by the parasite to survive within the RBC is critical. The Endoplasmic Reticulum (ER) is an organelle central to parasite biology, and its function is required for parasite survival. The ER serves as the starting point for protein trafficking to other organelles and to the host RBC, and stress response signaling from the ER is associated with parasites surviving treatment with the frontline anti-malarial Artemisinin. ER-resident chaperones support ER function and are therefore ideal candidates for exploring the parasite's biology. To this end, we have generated a conditional knockdown parasite line for PfJ2, a putative ER-resident Hsp40 expressed throughout the asexual cycle. Using this parasite line, we have confirmed that PfJ2 is an ER-resident protein and is essential for parasite survival inside the RBC. Specifically, knockdown of PfJ2 results in delayed parasite development during the trophozoite stage before failure to complete schizogony to form new invasive parasites. ER functions, such as protein trafficking and stress response, will be assayed during PfJ2 knockdown to investigate the chaperone's role in these processes. Additionally, PfJ2 uniquely contains both a J-domain and a thioredoxin-like domain, and we will explore how these domains contribute to PfJ2 function. By elucidating the role this essential chaperone plays in parasite biology, we will gain a better understanding of the mechanisms used by the parasite to survive in the RBC and cause disease.

1687

MALIAN CHILDREN WITH HEMOGLOBIN C OR S TRAIT RECOGNIZE FEWER EXTRACELLULAR PFEMP1S THAN CHILDREN WITH HEMOGLOBIN AA, BUT DIFFER IN RECOGNITION OF CD36-BINDING PFEMP1S

Mark A. Travassos[1], Amadou Niangaly[2], Jason A. Bailey[3], Andrea A. Berry[1], Amed Ouattara[1], Drissa Coulibaly[2], Kirsten E. Lyke[1], Matthew B. Laurens[1], Albert E. Zhou[1], Emily M. Stucke[1], Jozelyn Pablo[4], Algis Jasinskas[4], Rie Nakajima-Sasaki[4], Matthew Adams[1], Shannon Takala-Harrison[1], Bourema Kouriba[2], Abdoulaye K. Kone[2], J. Alexandra Rowe[5], Dapa A. Diallo[2], Ogobara K. Doumbo[2], Philip L. Felgner[4], Mahamadou A. Thera[2], Christopher V. Plowe[6]

[1]University of Maryland School of Medicine, Baltimore, MD, United States, [2]University Science, Techniques and Technologies of Bamako, Bamako, Mali, [3]Emmes Corporation, Rockville, MD, United States, [4]University of California Irvine, Irvine, CA, United States, [5]University of Edinburgh, Edinburgh, United Kingdom, [6]Duke University, Durham, NC, United States

Hemoglobin (Hb) C trait, like Hb S trait, protects against severe malaria in children and, in some Malian populations, against milder infections. Hb C trait alters the display of *Plasmodium falciparum* erythrocyte membrane protein-1 (PfEMP1), a family of parasite proteins expressed on the erythrocyte surface that mediates binding to endothelial receptors. Parasitized erythrocytes from individuals with hemoglobin C attach inefficiently to host endothelial receptors, potentially limiting host tissue sequestration and immune evasion. We hypothesized that sera from children with Hb C trait recognize fewer PfEMP1s than sera from children with Hb AA, given the altered PfEMP1 presentation in these individuals. We probed sera from Malian children with a protein microarray with 179 protein fragments from three variant surface antigen (VSA) families. Sera from children with uncomplicated malaria who had Hb C trait (N=14; ages 10-76 months) recognized fewer PfEMP1s than sera from similarly infected children with Hb AA (N=53; 7-98 months). This was true for both CD36-binding PfEMP1 fragments (14.0% of fragments recognized vs 68.6%, χ^2 test, P=3.4x10^{-13}) and non-CD36-binding PfEMP1 fragments (17.3% vs 75%, P=3.6x10^{-9}). Both groups recognized intracellular PfEMP1 fragments (81.8% vs 90.9%, P=0.38) and non-PfEMP1 VSAs (88.9% vs 88.9%, P=1) equally. Sera from uninfected children with Hb S trait (N=8; 6-55 months) recognized fewer PfEMP1s than sera from uninfected children with Hb AA (N=56; 7-76 months). This was true for CD36-binding PfEMP1 fragments (26.7% vs 47.7%, P=0.005), non-CD36-binding PfEMP1 fragments (11.5% vs 50.0%, P=2.1x10^{-5}), and intracellular PfEMP1s (13.6% vs 90.9%, P=2.9x10^{-7}). Interestingly, sera from these Hb S children recognized more CD36-binding PfEMP1 fragments than sera from uninfected children with Hb C trait (N=5; 8-31 months) (26.7% vs 8.1%, P=0.001). These results suggest that altered PfEMP1 presentation with Hb C or S trait reduces host immune recognition of these parasite proteins and that Hb C and S trait may affect PfEMP1 surface presentation in distinct ways that differentially alter humoral immune responses.

REVERSIBLE BRAIN SWELLING IN EXPERIMENTAL CEREBRAL MALARIA

Jessica Jin[1], Marek Cyrklaff[2], Kirsten Heiss[2], Sabine Heiland[3], Ann-Kristin Mueller[4], Johannes Pfeil[5], Martin Bendszus[1], Angelika Hoffmann[6]

[1]Department of Neuroradiology, Heidelberg University Hospital, Center For Infectious Diseases, Parasitology Unit, Heidelberg University Hospital, Heidelberg, Germany, [2]Center For Infectious Diseases, Parasitology Unit, Heidelberg University Hospital, Heidelberg, Germany, [3]Division of Experimental Radiology, Department of Neuroradiology, Heidelberg University Hospital, Heidelberg, Germany, [4]Center For Infectious Diseases, Parasitology Unit, Heidelberg University Hospital, German Center for Infection Research (DZIF), Heidelberg, Germany, [5]Center For Infectious Diseases, Parasitology Unit, Heidelberg University Hospital, Center For Childhood and Adolescent Medicine, General Pediatrics, Heidelberg University Hospital, German Center for Infection Research (DZIF), Heidelberg, Germany, [6]Department of Neuroradiology, Heidelberg University Hospital, Division of Experimental Radiology, Department of Neuroradiology, Heidelberg University Hospital, Heidelberg, Germany

Recently, reversible brain swelling has been identified in cerebral malaria patients using magnetic resonance imaging (MRI). It is unknown, if similar pathology occurs in experimental cerebral malaria (ECM). We thus examined immunized C57BL/6 mice after single vaccination with radiation-attenuated sporozoites (RAS) and naïve C57BL/6 mice upon infection with *Plasmodium berghei* ANKA- expressing mCherry. All mice were assessed according to the Rapid Murine Coma and Behavioral Scale (RMCBS) score once naïve mice showed ECM. We further analyzed brain pathology by using high resolution small animal MRI in order to assess brain swelling and blood-brain barrier disruption (BBBD), immunohistochemical staining for microglia, single plane illumination microscopy (SPIM) to locate parasites microscopically and correlative light and electron microscopy (CLEM) to study parasites on a nanoscopic level. In contrast to naïve mice, that showed extensive BBBD and brain swelling, all immunized mice survived the challenge and showed either reversible brain swelling and mild BBBD or no pathological signal alteration on MRI. Furthermore, less microglial activation was found in immunized mice compared to naïve mice. However, along the rostral migratory stream microglial activation appeared to be similar in both groups. Distinct brain areas with higher parasite density could be observed in both groups, although parasite distribution was more disseminated in naïve mice. By employing CLEM, we demonstrated that parasites have a high propensity towards the endothelium. In summary, we showed for the first time that reversible brain swelling also occurs in a mouse model of ECM by using advanced imaging techniques. We further identified hot spots of parasite accumulation and inflammation. This model may present a valuable tool to understand the mechanisms of reversible brain swelling in ECM.

MALARIA IN PREGNANCY INCREASES THE RISK OF PRETERM BIRTH IN ASSOCIATION WITH LONGITUDINAL CHANGES IN ANGIOGENIC, METABOLIC, AND INFLAMMATORY PATHWAYS

Robyn Elphinstone*[1], **Andrea Weckman***[1], Chloe McDonald[2], Vanessa Tran[2], Kathleen Zhong[2], Mwayiwawo Madanitsa[3], Linda Kalilani-Phiri[3], Victor Mwapasa[3], Feiko O. ter Kuile[4], Andrea L. Conroy[5], Kevin C. Kain[6]

[1]Department of Laboratory Medicine and Pathobiology, University of Toronto, Toronto, ON, Canada, [2]Sandra Rotman Centre for Global Health, University Health Network, Toronto, ON, Canada, [3]College of Medicine, University of Malawi, Blantyre, Malawi, [4]Department of Clinical Sciences, Liverpool School of Tropical Medicine, Liverpool, United Kingdom, [5]Department of Pediatrics, Indiana University School of Medicine, Indianapolis, IN, United States, [6]Tropical Disease Unit, Department of Medicine, University of Toronto, Toronto, ON, Canada

Malaria in pregnancy is associated with adverse birth outcomes, however the underlying mechanisms are poorly understood. Tight regulation of angiogenic, inflammatory and metabolic pathways are essential for healthy pregnancies. In this study we test the hypothesis that malaria disrupts these critical pathways in mid-pregnancy leading to preterm birth (PTB). Here we conduct a secondary analysis of a randomized trial of malaria prevention in pregnancy, to investigate the effect of malaria infection on the kinetics of biomarkers of angiogenesis and inflammation during pregnancy and their association with PTB. We assessed plasma biomarkers longitudinally over pregnancy in a cohort of HIV negative women (n=1755). Pregnancies were ultrasound dated and women were sampled at 13 to <24 weeks (Visit 1), 28 to <34 weeks (Visit 2), and/or 34 to <37 weeks (Visit 3). Biomarkers were analyzed by Luminex multiplex assays. Malaria prevalence was high with at least one episode of PCR-positive *Plasmodium falciparum* infection occurring in 69% (n=1210) of women,

and at least one smear-positive infection occurring in 28% (n=499) of women. Malaria infection before week 24 was associated with increased relative risk of PTB (adjusted RR, 95% CI: 1.29, 1.03-1.61, p=0.026). At all three visits over the course of pregnancy, malaria infection was associated with higher levels of CRP, IL-18BP, sTNFRII, and sEng. Using linear mixed effects modeling, PCR-positive malaria during the second trimester was associated with altered kinetics of CRP, CHI3L1, IL-18BP, sICAM-1, sTNFRII, sEng, Angptl3, and Leptin levels over pregnancy (χ^2 >11.0, p<0.01 for all). These data show that malaria infection in the second trimester of pregnancy is associated with altered kinetics of critical mediators of angiogenesis and inflammation over the course of pregnancy and an increased risk of PTB. Effective malaria treatment early in pregnancy may be required to prevent altered placental vascular development and poor birth outcomes.

INVESTIGATING THE ROLE OF VASCULAR ALPHA GLOBIN IN EXPERIMENTAL CEREBRAL MALARIA

Steven D. Brooks[1], Aline da Silva Moreira[2], Carlos Carhuas[1], Brant E. Isakson[3], Leonardo J. Carvalho[2], Hans C. Ackerman[1]

[1]National Institute of Allergy and Infectious Diseases, Rockville, MD, United States, [2]Instituto Oswaldo Cruz, Fiocruz Rio de Janeiro, Brazil, [3]University of Virginia School of Medicine, Charlottesville, VA, United States

Alpha globin was recently discovered in the endothelium of resistance arteries, where it regulates diffusion of nitric oxide (NO) through its interaction with endothelial nitric oxide synthase (eNOS) at the myo-endothelial junction (MEJ). During malarial infection, people with one or two deletions of the alpha globin gene are protected from severe complications, raising the question of whether this protection is conferred by changes to vascular endothelium, and if so, whether this pathway may present a novel target for a new adjuvant therapy in cerebral malaria. We are using dual genetic and pharmacologic approaches to disrupt the interaction between vascular alpha globin and eNOS in a murine model of experimental cerebral malaria (ECM) by infection with *P. berghei* ANKA. The genetic approach utilizes deletion of the alpha globin gene locus *Hba1* within the vascular endothelium; *Hba1* deletion increases arteriolar NO bioavailability, and our preliminary data shows robust expression of *Hba1* in cerebral arteries. For the pharmacologic approach, infected mice are treated with daily I.P. injections of HbaX, an alpha globin mimetic peptide. HbaX binds specifically with eNOS and blocks its association with alpha globin, effectively increasing NO bioavailability *in vivo* in healthy and hypertensive mice. Primary outcomes for the genetic and pharmacologic approaches in this ongoing study (completion expected August 2018) include: rapid murine coma score; time to onset of ECM symptoms and survival; laser speckle imaging of cerebral blood flow; assessment of blood brain barrier permeability; *ex vivo* reactivity of isolated cerebral arteries; and plasma and tissue measurement of NO bioavailability. We anticipate that this study will be highly informative towards understanding whether the protective effects of alpha globin deletion seen in malaria patients are conferred by changes within the vascular endothelium. Additionally, this study is interrogating whether targeting alpha globin to increase endogenous NO production within the cerebral vasculature can improve survival, cerebral blood flow, and vascular reactivity in a murine model of ECM.

THE ASSOCIATION OF BLOOD TRANSFUSION WITH OUTCOME AMONG AFRICAN CHILDREN HOSPITALIZED WITH *PLASMODIUM FALCIPARUM* MALARIA

Hans Ackerman[1], Aintzane Ayestaran[2], Christopher H. Olola[3], Kalifa Bojang[4], David J. Roberts[5], Terrie Taylor[6], Clarissa Valim[6], Climent Casals-Pascual[5]

[1]National Institutes of Health, Rockville, MD, United States, [2]Universitat de Barcelona, Barcelona, Spain, [3]Wellcome Trust Laboratories, Kilifi, Kenya, [4]Medical Research Council Unit, Fajara, Gambia, [5]University of Oxford, Oxford, United Kingdom, [6]Michigan State University, East Lansing, MI, United States

Infection with *Plasmodium falciparum* leads to severe malaria and death in approximately 445,000 children each year in sub-Saharan Africa. Blood transfusion may benefit some patients with malaria but could potentially harm others. To determine the hemoglobin concentrations at which blood transfusion is associated with improved survival of children admitted to hospital with *Plasmodium falciparum* malaria, we analyzed admissions to six tertiary care hospitals participating in the Severe Malaria in African Children network. Odds of in-hospital death associated with transfusion were estimated using site- and severity-adjusted analyses. Generalized additive models were used to estimate optimal hemoglobin transfusion thresholds. 25,893 pediatric patients were admitted to hospital with *P. falciparum* malaria, and 8,513 (32.8%) received a blood transfusion. Transfusion was associated with decreased odds of death in site-adjusted analysis (OR=0.82 [95%CI 0.71-0.94]). This association became stronger after adjustment for increased disease severity of transfused patients (OR=0.50 [95%CI 0.42-0.60]). Among all patients, transfusion was associated with improved survival when the hemoglobin was up to 77 g/L (95%CI: 65-110). Among those with impaired consciousness, transfusion was associated with improved survival at hemoglobin concentrations up to 105 g/L (95%CI: 71-115). Among those with hyperlactatemia, the association with improved survival persisted at even greater hemoglobin concentrations (lower bound 95%CI: 90 g/L). In conclusion, whole blood transfusion was strongly associated with improved survival among African children with *P. falciparum* malaria. Among those with impaired consciousness or hyperlactatemia, transfusion was associated with improved survival at hemoglobin concentrations well above the currently recommended transfusion threshold.

1692

MORPHOLOGICAL CHARACTERIZATION AND IDENTIFICATION OF CONSERVED *PLASMODIUM* BLOOD STAGE PROTEINS IN C*OLPODELLA* SP., FREE-LIVING RELATIVES OF APICOMPLEXANS

Tobili Y. Sam-Yellowe[1], Shanese James[1], Raghavendra Yadavalli[1], Hisashi Fujioka[2]

[1]Cleveland State University, Cleveland, OH, United States, [2]Case Western Reserve University, Cleveland, OH, United States

Colpodella sp. are the closest free-living ancestors of the apicomplexan phylum which contains important human pathogens such as *Plasmodium falciparum* and *Toxoplasma gondii*, causative agents of malaria and toxoplasmosis, respectively. *Colpodella*-like parasites infecting erythrocytes were reported in a human infection marked by low natural killer cells and anemia. *Colpodella* sp. possess a pseudoconoid, rhoptries, micronemes and in some species trichocysts at the apical end of the trophozoite. In a process similar to merozoite invasion in *P. falciparum*, contents of the rhoptries are emptied during myzocytosis. In this study, we investigated the morphological characteristics of *Colpodella* sp. using different staining techniques for light microscopy. Transmission electron microscopy was also performed for ultrastructural characterization. Antibodies specific to *Plasmodium* blood stage proteins were used in immunofluorescence assay. *Colpodella* trophozoites and cysts were stained by Giemsa, Wright's, Sudan IV, Picro-Sirius, Alum Carmine and hematoxylin and eosin (H&E) staining. We compared the clarity of morphological characteristics such as delineation of flagella, cytoplasmic structures, cyst features and the attachment junction formed during myzocytosis. Trophozoites and cysts were distinguished by all dyes except Alum Carmine and Sudan IV. Antibodies recognized several blood stage antigens including the high molecular weight rhoptry protein RhopH3 and SERA1. DNA sequencing of a polymerase chain reaction (PCR) amplified product obtained using primers targeting the *P. falciparum* RhopH3 gene confirmed the presence of RhopH3 in *Colpodella* sp. A combination of staining, immunological

and molecular protocols can be used to further investigate *Colpodella* sp. to gain insights regarding the potential for Colpodellid protists to be opportunistic human pathogens.

1693

DO ALPHA GLOBIN GENE VARIANTS AFFECT ENDOTHELIAL FUNCTION IN PATIENTS WITH SEVERE MALARIA?

Jessica Nino de Rivera[1], Matthew Grigg[2], Dongying Ma[1], Yu Yang[1], Bridget Barber[2], Timothy William[2], Kim Piera[2], J. Brice Weinberg[3], Tsin W. Yeo[2], Nicholas M. Anstey[2], Hans Ackerman[1]

[1]National Institutes of Health, Rockville, MD, United States, [2]Menzies School of Health Research, Darwin, Australia, [3]Duke University, Durham, NC, United States

The human alpha globin genes *HBA1* and *HBA2* are highly polymorphic, with deletions and sequence variants that decrease the transcription or synthesis of functional alpha globin protein causing a spectrum of alpha thalassemia syndromes. While some variants have been associated with decreased susceptibility to malaria, precise mechanisms of protection remain to be elucidated. Recently, alpha globin was discovered to be expressed in vascular endothelial cells where it regulates nitric oxide signaling. Genetic or pharmacologic inhibition of alpha globin expression increased nitric oxide signaling in intact vessels, therefore we hypothesize that human polymorphisms that inactivate alpha globin will increase endothelial nitric oxide signaling. This is relevant to the pathogenesis of malaria where the loss endothelial nitric oxide signaling may contribute to adhesion of infected blood cells, occlusion of small vessels, and impairment of vasoregulation. To address the hypothesis that alpha globin regulates endothelial nitric oxide signaling, we will genotype alpha globin gene mutations in a case control study of moderately severe and severe malaria patients infected with *Plasmodium falciparum*, *Plasmodium vivax* or *Plasmodium knowlesi* from Timika, Indonesia and Sabah, Malaysia. We will genotype the -3.7, -4.2, --SEA, and --FIL deletions and the Constant Spring and Adana sequence variants. We will use a droplet digital PCR approach to quantify precisely the number of variant alleles at this duplicated tandem gene locus. We will analyze the association of alpha globin gene deletions/variants with previously performed functional measures of vascular endothelial function: peripheral arterial tonometry and skeletal muscle reperfusion kinetics. In addition, we will examine biomarkers of endothelial activation such as angiopoietin-2 which is regulated by nitric oxide and elevated in severe malaria. These studies will extend our understanding of the role of endothelial alpha globin in nitric oxide signaling and determine what impact alpha globin variants have on endothelial function during severe malaria.

1694

THERE IS RIBOSOME STALLING IN *PLASMODIUM FALCIPARUM*

Slavica Pavlovic Djuranovic, Sergej Djuranovic

Washington University School of Medicine, St. Louis, MO, United States

Ribosomes are main players in protein synthesis, and their function can be interrupted due to damaged mRNA, insufficient availability of tRNAs and amino-acids or genetic errors. Most of the organisms have evolved mechanisms to recognize stalled ribosomes and initiate pathways that involve conserved eukaryotic proteins Pelota in mammals (Dom34 in yeast) and Hbs1. In many translation-inhibiting stress conditions, free ribosomal subunits reassociate to form a large pool of non-translating 80S ribosomes. The subunits of these inactive ribosomes need to be mobilized for translation restart upon stress relief. In yeast, the Dom34-Hbs1 complex, have been shown to split ribosomes stuck on mRNAs. Interestingly, to date in *Plasmodium falciparum* genome putative PELO gene is annotated but not HBS1L. In our recent work, we have shown that polyA stretches longer than 12 adenosines in a row cause stalling in most eukaryotes resulting in mRNA decay and protein degradation. Surprisingly, the same sequences are efficiently translated in *P. falciparum*. To induce ribosome stalling we used the fact that *P. falciparum* must acquire isoleucine exogenously. *P. falciparum* is auxotrophic for most amino acids. Degradation of host erythrocyte hemoglobin is the source of most of the amino acid except for isoleucine because this amino acid is not present in adult human hemoglobin. When isoleucine is withdrawn from the culture medium of intraerythrocytic *P. falciparum*, the parasite slows its metabolism, and isoleucine-starved parasites remain viable for 72 h. During the parasite hibernation, the ribosomes are stalled. Using CRISPR/Cas9 technique, we tagged PELO gene with 2HA tags. Successfully tagged PELO gene was expressed in *P. falciparum*. Using polysome profiling, we showed the interaction of Pelota protein with stalled ribosomes in cultures deprived of isoleucine compared to control culture supplemented with it. The open question is does Pelota have interaction partner because in most eukaryotes most the partner in crime is Hbs1 or it works on its own.

1695

IS COMPLICATED MALARIA AN IMPORTANT CAUSE OF ILLNESS AMONG ADULTS IN KAMPALA, UGANDA?

Peterson Stephen Kyebambe, Julius Kabbali Kuule, Joseph Beinomugisha, Douglas Kenneth Mutenyo

Naguru Referral Hospital, Kampala, Uganda

Malaria is one of the most important diseases in the world with more than 3 billion people at risk of infection. The largest burden is still in Sub-Saharan Africa. In Uganda, malaria, has persisted as the most important cause of mortality and morbidity despite years of efforts towards its reduction and eventual eradication. Worldwide, most of the cases of severe malaria have been documented in children but adults are not spared either. We set out to out to find out the extent to which patients on the adult (12 years and above) medical ward in our hospital exhibit features of severe malaria. Diagnosis was based on clinical signs and positive Rapid Diagnostic Test (RDT) and blood slide for malaria. We analysed charts of patients who were admitted from January to March 2018. Out of a total 133 admitted,22 had features of complicated malaria as below: Seven (31%) had thrombocytopenia,6 (27%) had anemia,4 (18%) had respiratory distress,4 (18%) had altered mentation,2(9%) had hypoglycemia,1 (4.5%) were in shock and 1 (4.5%) had renal insufficiency. All were treated for malaria using standard intravenous artesunate dosing. Twenty cured,1 was referred and 1 died. The above findings indicate that indeed complicated malaria is an important cause of morbidity and even mortality among adult patients in Kampala, a high endemicity area.

1696

PREVALENCE OF MOLECULAR MARKERS ASSOCIATED WITH ARTEMISININ, LUMEFANTRINE AND AMODIAQUINE RESISTANCE IN PRE-TREATMENT ISOLATES FROM TWO THERAPEUTIC EFFICACY MONITORING SITES IN GUINEA, 2016

Abdoul Habib Beavogui[1], Abdoulaye Doumbouya[1], Alioune Camara[2], Julia Kelley[3], Aissata Fofana[4], Eldin Talundzic[5], Abdoulaye Sarr[6], Amadou Sow[1], Alexandre Delamou[1], Mateusz M. Plucinski[7]

[1]Mafèrinyah Rural Health Research Center, Conakry, Guinea, [2]National Malaria Control Program, Conakry, Conakry, Guinea, [3]Atlanta Research and Education Foundation and Malaria Branch, Centers for Disease Control and Prevention, Atlanta, GA, United States, [4]RTI International, Conakry, Guinea, [5]Malaria Branch, Centers for Disease Control and Prevention, Atlanta, GA, United States, [6]U.S. President's Malaria Initiative, Centers for Disease Control and Prevention, Conakry, Guinea, [7]Malaria Branch and U.S. President's Malaria Initiative, Centers for Disease Control and Prevention, Atlanta, GA, United States

In Guinea, artemisinin-based combination therapy is the first-line antimalarial treatment for uncomplicated *Plasmodium falciparum* infection. There are limited data on the prevalence in Guinea of polymorphisms in the *pfk13* gene (artemisinin resistance) and the *pfmdr1* gene (amodiaquine

and lumefantrine resistance). Since 2015, the National Malaria Control Program has implemented yearly therapeutic efficacy studies rotating between four sentinel sites in the country. We isolated DNA from 444 samples from study participants, including 421 pretreatments and 22 day-of-late treatment failure samples collected as part of the 2016 round of therapeutic efficacy studies in Mafèrinyah and Labé Health Districts. The *pfk13* and *pfmdr1* gene were amplified, sequenced and analyzed for polymorphisms. Of the 397 samples successfully analyzed, the majority of pretreatment (99%, 369/374) and all day-of-late treatment failure (100%, 22/22) samples were wild type for *pfk13*. Five pretreatment samples (1%, 5/374) carried synonymous mutations in the Kelch-propeller domain, including three in the artemether-lumefantrine arm (L429L, E509E and V510V) and two in the artesunate-amodiaquine arm (C469C and G496G). All five patients with *pfk13* mutations were slide-negative on Day 3 and finished 28-day follow-up with adequate clinical and parasitological response. The NFD haplotype was the predominant *pfmdr1* haplotype, present in 48% (189/391) of pretreatment samples, followed by the NYD haplotype, present in 33% (128/391) of pretreatment samples. Efficacy studies in 2016 in Mafèrinyah and Labé Health Districts showed genetic evidence of susceptibility to artemisinins, consistent with clinical outcome data showing 100% Day 3 clearance rates. Despite the absence of non-synonymous *pfk13* mutations, a substantial proportion of pretreatment isolates had *pfmdr1* haplotypes previously associated with decreased lumefantrine susceptibility. Continued molecular monitoring is required at country level to ensure timely detection of antimalarial drug resistance and resistance-associated mutations.

1697

GENOMIC PROFILE OF *PLASMODIUM FALCIPARUM* PARASITES LACKING HISTIDINE-RICH PROTEIN (*PFHRP2*) FROM ERITREA

Khalid B. Beshir[1], Araia Berhane[2], Selam Mihreteab[2], Amy Ibrahim[1], Ernest DiezBenavent[1], Nuno Sepulveda[1], Colin Sutherland[1], Taane Clark[1], Susana Campino[1]

[1]London School of Hygiene & Tropical Medicine, London, United Kingdom, [2]Communicable Diseases Control Division, Ministry of Health, Asmara, Eritrea

Recent emergence of *Plasmodium falciparum* lacking *hrp2* may have diverse consequences for the parasite. Deleterious mutations can generate a strong selection pressure to balance the detrimental effects through compensatory genetic changes. It has been predicted that as transmission declines the parasite population shifts towards parasites lacking *hrp2*, presumably due to the selective pressure of HRP2-RDT results determining the likelihood of treatment. *Hrp2*-deleted parasites have been shown to have lower multiplicity of infection compared to *hrp2*-harbouring parasites, but it is not clear whether such parasites also have lower genetic diversity and whether they are more likely to harbour wild-type alleles of drug resistance-associated genes. In this study, we compared genomic data for *hrp2*-deleted and *hrp2*-normal samples from Eritrea. *P. falciparum* DNA extracted from dried blood spots was selectively whole genome amplified and sequenced on an Illumina platform, leading to the first genomic data of *P. falciparum* parasite isolates from Eritrea. Several genes of antimalarial drug resistance markers including *pfcrt*, *pfmdr1*, *pfdhfr*, *pfdhps*, *pfk13*, *pfAP2μ*, *pfubp1*, *pfATP6* and *pfnhe-1* were compared between the two parasite groups. We also analysed genes associated with cerebral malaria (CM), as *hrp2* has been reported to play a role in manifestation of CM. Finally, the genetic diversity within and between the two parasite groups, including variant antigen repertoires, was examined. Drug resistance marker alleles as well as other novel mutations from both *hrp2*-deleted and *hrp2*-positive parasite isolates will be reported. Initial findings show that both parasite groups carried the chloroquine-resistant haplotype *pfcrt* CVIET and the sulfadoxine-pyrimethamine resistance-associated allele *dhps* 540E. The implication of the findings on malaria control and elimination will be discussed.

1698

EFFICACY OF ARTESUNATE-AMODIAQUINE IN THE TREATMENT OF UNCOMPLICATED FALCIPARUM MALARIA IN MADAGASCAR

Raobela Oméga, Arsene Ratsimbasoa

National Malaria Control Program, Antananarivo, Madagascar

In Madagascar, artesunate-amodiaquine (ASAQ) are the first line treatment recommended in uncomplicated falciparum malaria. Since 2006, only two clinical drug efficacy studies have been conducted to assess the efficacy of ACTs. In this context, new data about the efficacy of the drug combinations currently used to treat malaria are needed. Cohorts' studies of therapeutic efficacy of ASAQ were conducted in six sites in different epidemiological patterns, whose, Vangaindrano, Tsiroanomandidy in 2012, Mandoto, Marovoay in 2013, Ifanadiana, Maevatanana in 2016. The 2009 WHO protocol for monitoring antimalarial drug efficacy was followed. 358 patients were enrolled. Their ages ranged from 6 months to 56 years (median: 8 years). Patients enrolled in Vangaindrano and Ifanadiana were all aged <15 years. The mean of the parasite density at day 0 was 17,440 parasites/µl of blood (95%CI: 5,164-29,734, range: 510-356,250). The combination was well tolerated. Few adverse events in gastrointestinal transit, in the central nervous systems and in musculoskeletal system were observed, whose, 11,45% (41/358) patients, 2,51% (9/358) and 2,51% (9/358) respectively. The median hemoglobin concentration, among patients with available data, significantly increased from 10,61 g/dL on day 0 to 11,92 g/dL on day 28. The overall efficacy of ASAQ after PCR correction was 98,2% (95% IC: 90,6 - 99,7). According to years, the PCR-corrected day 28 cure rates were 94,4% (95% IC: 88,4 -97,4) in 2012; 100% (95% IC: 96,9 - 100) in 2013 and 100% (95% IC: 96,6 - 100) in 2016. There was no case of early treatment failure (ETF); two cases of Late Parasitological Failure (LPF), determined by msp1/msp2genotyping, the first was a true recrudescence, the second was classified as reinfected and one case of Late Clinical Failure (LCF) were observed and also was classified as reinfected. ASAQ remains highly efficacious in uncomplicated falciparum malaria in Madagascar. According to our results, the increased incidence of falciparum malaria cases observed recently seems not related to clinical treatment failure of the first line treatment promoted since 2006.

1699

ARTEMISININ RESISTANCE? MIND THE TRAFFIC ...

Colin J. Sutherland, Ryan C. Henrici

London School of Hygiene & Tropical Medicine, London, United Kingdom

Artemisinin susceptibility in *Plasmodium falciparum* is modulated by mutations in the gene *pfk13*, which encodes a kelch propeller domain protein of unknown function. Reduced susceptibility is demonstrated *in vitro* by elevated parasite survival after short exposures to physiologic concentrations of drug in the early ring stage. Using CRISPR-Cas9 genome editing, we provide the first evidence of a similar but K13-independent *in vitro* artemisinin resistance caused by a single base change in the locus encoding the AP-2 adaptor complex mu-subunit (*pfap2mu*). Through extensive fluorescence and electron microscopy and proteomics, our functional characterisation of PfAP2mu validates that gene as encoding a clathrin-independent, non-canonical AP-2 trafficking factor that interacts with K13 and other important factors at a distal face of the ER and is essential for asexual parasite survival. We provide evidence that disruption of trafficking in early rings initiates an ER-based stress response that underlies artemisinin resistance and induced dormancy. A model depicting a role for ER trafficking components in ring-stage artemisinin action is proposed and implications for controlling multi-drug resistance in natural parasite populations will be discussed.

1700

TARGETED DEEP AMPLICON SEQUENCING ANALYSIS OF *KELCH 13* AND *CYTOCHROME B* GENES IN *PLASMODIUM FALCIPARUM* ISOLATES FROM ERITREA

Mariangela L'Episcopia[1], Michela Menegon[1], **Carlo Severini**[1], Abduselam M. Nurahmed[2], Albadawi A. Talha[3], Bakri Y. Nour[4], Julia Kelley[5], Dhruviben Patel[5], Shashidhar Ravishankar[5], Naomi Lucchi[6], Venkatachalam Udhayakumar Udhayakumar[6], Eldin Talundzic Talundzic[6]

[1]Istituto Superiore di Sanità, Rome, Italy, [2]Cansford Laboratories, Pentwyn Business Centre, Cardiff, United Kingdom, [3]Faculty of Medical Laboratory Science, University of Gezira, Gezira, Sudan, [4]University of Gezira, Blue Nile Research National Institute for Communicable Diseases, Gezira, Sudan, [5]Atlanta Research and Education Foundation, Veterans Affairs Medical Center, Atlanta, GA, United States, [6]Centers for Disease Control and Prevention, CGH, DPDM, Atlanta, GA, United States

The emergence in Southeast Asia of *Plasmodium falciparum* parasites resistant to artemisinins poses a threat to malaria control and prevention strategies. Several polymorphisms in the *P. falciparum kelch 13* (*k13*) gene have been linked to artemisinin resistance (ART-R). Similarly, polymorphisms in *cytochrome b (cyt b)* gene have been associated with atovaquone resistance (ATQ-R), which is a component drug in malarone, used for prophylaxis and as one of the primary treatments for travelers diagnosed with *P. falciparum* in the U.S. and Europe. Molecular surveillance for drug resistance markers is valuable in developing guidelines for treatment and prophylaxis in the U.S and other countries. Next generation sequencing (NGS) have helped to develop a multiplex targeted genome based method at CDC for the characterization and early detection of drug resistance polymorphisms, including mixed infection genotypes. In this study, we used this high-throughput, standardized molecular surveillance system, Malaria Resistance Surveillance (MaRS), to screen 148 *P. falciparum* isolates from Eritrea for polymorphisms in *k13* and *cyt b*. The blood samples were collected from malaria patients attending the referral hospitals and health facilities located in the study area. No mutations associated with ART-R or ATQ-R were observed. However, eleven non-synonymous and two synonymous polymorphisms that have not been linked to ART-R were observed in *k13*. Seventy of 148 (48%) had a polymorphisms in the *k13* gene, of which 4 of 148 (2%) were minor alleles (with an allele frequency at or below 50 percent). The K189**T** polymorphism was found in 59 of 148 (40%) of samples. The D281**V** polymorphism was found in 8 out of 148 (5%) of samples. The remaining 9 non-synonymous polymorphisms were observed in 4 or fewer samples. No non-synonymous polymorphisms were observed in the *cyt b* gene. Only the synonymous V127**V** and L230L polymorphisms were found in one sample each. As demonstrated in the presented study, continued monitoring using MaRS for early detection of drug resistance associated polymorphisms will be useful to develop treatment and prevention guidelines for malaria.

1701

DISTRIBUTION AND ORIGINS OF PFCRT MUTATIONS ASSOCIATED WITH PIPERAQUINE RESISTANCE IN CAMBODIA

Biraj Shrestha[1], Matthew Adams[1], Christian Parobek[2], Huy Rekol[3], Soklyda Chann[4], Michele D. Spring[4], Mariusz Wojnarski[4], David L. Saunders[4], Philip L. Smith[4], Chanthap Lon[4], Jessica T. Lin[2], Shannon Takala-Harrison[1]

[1]University of Maryland Baltimore, Baltimore, MD, United States, [2]University of North Carolina at Chapel Hill, Chapel Hill, NC, United States, [3]National Center for Parasitology Entomology and Malaria Control, Phnom Penh, Cambodia, [4]Armed Forces Research Institute of Medicine Sciences, Bangkok, Thailand

Resistance to both the artemisinins and key partner drugs, such as piperaquine, has become well-established in regions of Cambodia and has spread to some neighboring countries. We have recently shown that the *Plasmodium falciparum* chloroquine resistance transporter (PfCRT) F145I mutation is associated with reduced susceptibility to piperaquine, tends to occur on a background of amplified *plasmepsin II* (*pfpm2*), and confers an additional degree of resistance above that of amplified *pfpm2* alone. To better understand the timing of the emergence of this mutation and other PfCRT mutations associated with piperaquine resistance, we examined parasites from 469 clinical infections collected from eight provinces during past and ongoing studies in Cambodia, to estimate the distribution of PfCRT mutations over time and their origins. Parasites were available from northern provinces of Cambodia from 2009-2014, from western provinces from 2009-2011, and from the south in 2011-2012. We used quantitative PCR, or read coverage for samples with whole genome sequence available, to estimate *pfpm2* copy number. PfCRT F145I was genotyped by pyrosequencing. In this dataset, amplified *pfpm2* was observed in <1% of samples in 2009 and increased in frequency over time, reaching a prevalence of 75% in Northern Cambodia by 2014. PfCRT F145I was first observed in the Oddar Meanchey province in 2013 (25% prevalence) and was present in 33% of parasites sampled from that study site in 2014. Of the 23 infections with the PfCRT F145I mutation, 21 occurred on a background of amplified *pfpm2*. PacBio amplicon sequencing is underway to sequence the entire *pfcrt* gene to estimate the prevalence of other PfCRT mutations reported to be associated with piperaquine resistance, in both archived and more recent *P. falciparum* infections. Markers flanking and in linkage disequilibrium with the *pfcrt* gene will be examined to determine the origins of observed mutations. This work will provide insights into the emergence and spread of PfCRT mutations contributing to piperaquine resistance.

ACQUISITION OF POINT MUTATIONS IN *DIHYDROPTEROATE SYNTHETASE* GENE DRIVE COPY NUMBER VARIATIONS OF GTP-CYCLOHYDROLASE *1* (*GCH1*) GENE IN GHANAIAN *PLASMODIUM FALCIPARUM* ISOLATES

Musah Osei[1], Nancy O. Duah[2], Felix Ansah[3], Sena A. Matrevi[3], Kwaku P. Asante[1], Gordon A. Awandare[3], Neils B. Quashie[4]

[1]Kintampo Health Research Centre, Brong Ahafo, Ghana, Kintampo, Ghana, [2]Department of Epidemiology, Noguchi Memorial Institute for Medical Research, College of Health Sciences, University of Ghana. Legon, Ghana, Accra, Ghana, [3]West African Centre for Cell Biology of Infectious Pathogens, Department of Biochemistry, Cell and Molecular Biology, School of Biological Sciences, College of Basic and Applied Sciences, University of Ghana, Accra, Ghana, [4]Centre for Tropical Clinical Pharmacology and Therapeutics, School of Medicine and Dentistry, College of Health Sciences, University of Ghana, Accra, Ghana

Sulfadoxine-pyrimethamine (SP) is used for Intermittent Preventive Treatment in pregnant women (IPTp) as well as for seasonal malaria chemoprophylaxis (SMC) in children in Ghana. *Plasmodium falciparum* resistance to SP has been linked to point mutations in the parasite's dihydropteroate synthase *(pfdhps)* and dihydrofolate reductase *(pfdhfr)* genes which encodes the protein targets of SP action. There is recent evidence from South East Asia of the amplification of GTP cyclohydrolase 1 (*pfgch1*) gene, which encodes for the first enzyme in the parasite *denovo* folate synthesis pathway in parasites which harbor the SP resistance point mutations including I164L. The point mutations make the parasites less fit, but the acquisition of multiple copies of the *gch1* gene may compensate for this fitness cost or directly enhance SP resistance. This study determined the association between *pfgch1* copy number variations (CNV) and SP resistance molecular markers in clinical isolates in Ghana. The findings are important for policy makers of malaria chemotherapy in Ghana. Two hundred and two (202) blood samples collected from children aged 14 years and below with uncomplicated malaria, presenting at health centres in Accra, Kintampo, Cape-Coast and Navrongo were used for this study. Quantitative real-time PCR was used to estimate *pfgch1* copy number and nested PCR followed by Sanger sequencing for detection of mutations in *pfdhps* and *pfdhfr* genes. It was observed that 92.6% (187/202) and 7.4% (15/202) of the parasite isolates harbored

single and double copies of the *gch1 g*ene respectively. SP resistance markers, I51, R59 and N108 were observed except L164, R50 and T163. A significant correlation was observed between the *gch1* CNV and *pfdhps* E540 (P=0.001) and G581 (P=0.002), but none for the *pfdhfr* mutations. Findings from this study have that *pfdhps* E540 and G581 correlated with increased *gch1* copy number may imply that *gch1* may compensate for the fitness cost of parasites harboring these mutations. Continuous monitoring of the *gch1, pfdhfr and pfdhps* genes is recommended and further studies to discover component drugs to target the *gch1* gene product is required.

1703

DRUG SENSITIVITIES AND MECHANISMS OF RESISTANCE IN UGANDAN *PLASMODIUM FALCIPARUM* ISOLATES TO LEAD ANTIMALARIALS IN THE MEDICINES FOR MALARIA VENTURE DEVELOPMENT PIPELINE

Stephanie A. Rasmussen[1], Patrick K. Tumwebaze[2], Melissa D. Conrad[3], Oswald Byaruhanga[2], Thomas Katairo[2], Martin Okitwi[2], Samuel L. Nsobya[2], Benjamin Blasco[4], Philip J. Rosenthal[3], Roland A. Cooper[1]

[1]Dominican University of California, San Rafael, CA, United States, [2]Infectious Diseases Research Collaboration, Kampala, Uganda, [3]University of California, San Francisco, CA, United States, [4]Medicines for Malaria Venture, Geneva, Switzerland

New antimalarial drugs are urgently needed. To characterize the Medicines for Malaria Venture pipeline of lead antimalarials, we assessed the *ex vivo* drug sensitivity of fresh *Plasmodium falciparum* clinical isolates from Tororo and Busia districts in eastern Uganda and analyzed sequences of parasites with altered sensitivity. *Ex vivo* drug sensitivities were assessed with 72 h growth inhibition (IC50) assays on 188 clinical isolates collected from 2015-2017. Mean IC50 values were generally near those reported for laboratory isolates, yet outliers were identified. Positive correlations between IC50s were seen for compounds with shared targets, notably predicted inhibitors of PfATP4 (KAE609, SJ733, and PA92), PfDHODH (DSM265, DSM421, and DSM632), and PfPI4K (UCT048 and UCT943). For outliers, defined as an IC50 diverging by at least 2.5-fold from the geometric mean IC50, we sequenced putative drug targets/resistance mediator alleles. Notable outliers were seen for inhibitors of PfATP4 (KAE609, SJ733, and PA92), PfCYTb (ELQ300), PfDHFR (P218), PfCARL (KAF156), PfPI4K (UCT048 and UCT943), and V-type H^+ -ATPase (AZ253). For PfATP4, a G223S single nucleotide polymorphism (SNP) was found in outliers for PA92, SJ733, and KAE609. A SNP at this same allele, G223R, was previously selected in laboratory strains with a KAE609 analog. For PfCYTb, the isolate showing the highest ELQ300 IC50 exhibited a novel A205V mutation, predicted to be in the ELQ300 binding site. For PfDHFR, SNPs N51I, C59R, S108N, and I164L associated with resistance to pyrimethamine, were highly prevalent, with I164L more common than in other tested parasites in this region, and associated with the highest IC50s for P218. Sequencing of *pfpi4k*, *pfcarl, pf V-type H^+-ATPase*, and other polymorphisms is ongoing. Data available to date show variations in sensitivity to new antimalarial leads in parasites now circulating in Uganda; some of these variations appear to be explained by genetic polymorphisms in predicted drug targets. Regular, sustained study of the sensitivity of field parasites to new compounds will be essential in establishing next generation antimalarial therapies.

Continued malaria elimination and eradication efforts require the development of new drugs acting on all stages of the parasite lifecycle. Compounds that target liver stage development are particularly valuable as chemopreventative agents. In addition to providing prophylactic protection, the parasite might be less capable of evolving resistance to liver-stage drugs. During the liver stage a significantly smaller parasite population is exposed to drug pressure, reducing the probability of selecting for resistant forms. To address the need for liver-stage active compounds, a *P. berghei* - hepatic cell culture system was used to screen a commercially available library. Confirmed hit compounds were further screened for activity against asexual blood stage parasites to aid in target identification efforts. Interestingly, a number of molecules were only active against liver stages suggesting that they affect unique targets that are not essential during asexual development. Here we present target identification studies for one of the dual liver and asexual-active molecules, MMV1454442. In preliminary functional assays, MMV1454442 had markedly reduced activity in transgenic parasites that express *S. cerevisisae* dihydroorotate dehydrogenase (ScDHODH), suggesting a mitochondrial mode of action. To further elucidate the target of this compound, *in vitro* resistant lines were generated and whole genome sequencing used to identify genetic variants contributing to the resistance phenotype. Resistant clones had either a point mutation resulting in an F188I amino acid change in *P. falciparum* DHODH or evidence of increased copy number encompassing this locus. Interestingly, MMV1454442 represents a new scaffold of DHODH inhibitors and would not have been predicted to be a DHODH inhibitor based on structure alone. Further studies to understand the interplay of diverse DHODH inhibitors and resistance mutations are ongoing. DHODH is a well-validated antimalarial target, and this study highlights the importance of this pathway particularly in developing chemotherapeutic interventions that target pre-erythrocytic stages of the lifecyle.

DISAPPEARANCE OF CHLOROQUINE RESISTANT *PLASMODIUM FALCIPARUM* IN EASTERN UGANDA

Patrick K. Tumwebaze[1], Oswald Byaruhanga[1], Martin Okitwi[1], Thomas Katairo[1], Melissa Conrad[2], Stephanie Rasmussen[3], Samuel L. Nsobya[1], Roland A. Cooper[3], Philip J. Rosenthal[2]

[1]Infectious Disease Research Collaboration, Kampala, Uganda, [2]University of California, San Francisco, CA, United States, [3]Dominican University, San Rafael, CA, United States

Standard treatment for malaria in Africa has changed from chloroquine (CQ) and/or sulfadoxine- pyrimethamine to artemisinin-based combination therapies (ACTs) over the last 10-15 years, accompanied by reemergence of CQ-sensitive parasites. In Uganda, the first-line treatment changed to artemether-lumefantrine in 2004, with gradual implementation thereafter; alternative regimens are artesunate-amodiaquine and dihydroartemisinin-piperaquine. We assessed *ex vivo* drug sensitivity and molecular markers to gain insight into drug sensitivity over time in eastern Uganda. As previously reported, the geometric mean *ex vivo* IC_{50} for CQ of 408 *P. falciparum* isolates collected in Tororo in 2010-13 was 248 nM (cut-off for CQ resistance 80 nM). We reinitiated regular assessment of drug sensitivities in Tororo and Busia districts in 2016. The geometric mean IC_{50} for 182 isolates collected during 2016-17 was 20 nM. Trends toward increased CQ sensitivity continued, with the percentage of isolates with IC_{50} > 80 nM decreasing from 31% to 16% to 10% to 8% over 6 month intervals in 2016-17. Molecular data showed tight correlation between the *pfcrt* 76T mutation and CQ IC_{50}> 80 nM. Isolates were generally sensitive to monodesethyl amodiaquine, piperaquine, lumefantrine, and dihydroartemisinin, with improved sensitivity to monodesethyl amodiaquine and piperaquine, decreased sensitivity to lumefantrine, and no change for dihydroartemisinin since 2010-13. Sensitivities to these drugs did not change noticeably over 2016-17. Molecular markers associated with decreased sensitivity to artemisinins (K13), lumefantrine (*pfmdr1* amplification), and piperaquine (*plasmepsin 2* amplification) have been uncommon in Uganda, and not clearly associated with *ex vivo* drug sensitivity. Overall, parasites now circulating in eastern Uganda are sensitive to a range of antimalarials, and the large majority are now sensitive to CQ. Trends toward increasing resistance to ACTs in SE Asia are of great concern, but current widespread improved drug sensitivity now offers an opportunity for drug-based interventions to better control malaria in Africa.

1706

EFFECT OF THE QUINOLINE RING SUBSTITUTION PATTERN ON THE ACTIVITY OF REVERSED CHLOROQUINE COMPOUNDS

Katherine M. Liebman[1], Jane X. Kelly[2], Yuexin Li[2], Alvin W. Annen[2], Michael C. Liebman[2], David H. Peyton[2]

[1]DesignMedix, Inc., Portland, OR, United States, [2]Portland State University, Portland, OR, United States

Antimalarial drug resistance is a serious global problem, and so there remains an ongoing need for new antimalarial drug candidates that will be active against drug-resistant parasites. Historically, chloroquine (CQ) was one of the most important antimalarials, but its utility is now greatly limited by chloroquine resistance (CQR). We have already shown that attachment of a chemosensitizer (reversal agent, RA) to the side chain of a chloroquine-like moiety results in molecules active against CQR strains of *P. falciparum* malaria; we have termed these molecules reversed chloroquines (RCQs). We here examine the effect of the quinoline ring system substitution pattern upon *in vitro* antiplasmodial activity of the RCQs. The compounds presented here include those bearing a substituent in the quinoline 2-, 5, 6-, 7-, and/or 8-position, and include those with chloro, bromo, iodo, fluoro, nitro, trifluoromethyl, methyl, and methoxy substituents. For RCQs, 2-, 5-, and 8- substituents were found to decrease *in vitro* antiplasmodial activity against *P. falciparum* relative to 7-chloro substitution, whereas 6- and 7- substituted compounds with the various substituents have in many cases similar activity to that of 7-chloro substituted RCQs. Little difference was observed between 6- and 7- substitution, or between chlorine and a methyl group in position 6. In most cases these effects on activity are directionally similar to those observed for chloroquine analogs without an attached reversal agent, but the magnitude of the effect is generally smaller, suggesting that the activities of RCQs are less affected by modifications to the quinoline ring system than are chloroquine analogs without an attached reversal agent.

1707

MOLECULAR SURVEILLANCE FOR ARTEMISININ RESISTANCE ASSOCIATED *KELCH 13* MUTATIONS IN *PLASMODIUM FALCIPARUM* SAMPLES FROM THE STATE OF RORAIMA, BRAZIL

Naomi W. Lucchi[1], Rispah Abdhallah[1], Jaime Louzada[2], Ira Goldman[1], Joseli Oliveira-Ferreira[3], Venkatachalam Udhayakumar[1]

[1]Centers for Disease Control and Prevention, Atlanta, GA, United States, [2]Federal University of Roraima, Roraima, Brazil, Roraima, Brazil, [3]Institute Oswaldo Cruz- Fiocruz, Rio De Janeiro, Brazil

Roraima State is located in the northern region of Brazil bordering both Venezuela and Guyana and is part of the Guiana Shield. Although the majority of autochthonous malaria cases in Roraima are predominately *Plasmodium vivax* infections, recent observations have revealed an increase *in P. falciparum* cases originating mainly from Guyana and Venezuela, with a high proportion of these due to miners moving between these regions. Given that the C580**Y** polymorphism in the *kelch 13* propeller domain of *P. falciparum*, a confirmed marker of artemisinin resistance, was found in about 5% of parasites in Guyana, there is a concern that this mobile population could contribute to the spread of drug resistant parasites in the region. In order to determine if *kelch 13* mutations associated with artemisinin resistance are present in Roraima State, we initiated a molecular surveillance study. In 2016-2017, a total of 429 samples were collected from three sites, namely: Pacaraima (at the border with Venezuela; 129), Boa Vista (the state capital; 243) and Rorainopolis (57). Dried blood spots were collected for molecular diagnosis and characterization of drug resistance markers. Among these 429 samples, there were 136 PCR confirmed *P. falciparum* positive samples which were sequenced for known polymorphisms in both the *kelch 13* propeller domain and the *Pfmdr-1* gene using the Sanger sequencing method. We did not observe any mutations in the *kelch 13* propeller domain in the 126 samples that were successfully sequenced. A total of 115 samples were successfully sequenced for *Pfmdr-1* gene; we observed two *Pfmdr-1* mutant genotypes: 184**F**/1042**D**/1246**Y** (triple-mutant) and 184**F**/1034**C**/1042**D**/1246**Y** (quadruple-mutant) at frequencies of 83% and 17%, respectively. These results suggest that artemisinin resistance mutations found in Guyana have not spread to Roraima State of Brazil. However, given the high mobility of people in this state and the neighboring countries, continued molecular surveillance is essential to detect any potential migration or local emergence of artemisinin resistant mutation in this region.

1708

THE ACT PARTNER DRUG MOLECULAR SURVEYOR: ONLINE MAPPING DATABASE FOR *PLASMODIUM FALCIPARUM* DRUG RESISTANT MOLECULAR MARKERS

Sabina D. Otienoburu[1], Ignacio Suay[2], Steven Garcia[2], Suttipat Srisutham[3], Carol Sibley[2], Georgina Humphreys[2]

Tropical Medicine Research Unit, Faculty of Tropical Medicine, Mahidol University, Bangkok, Thailand

Comparing the prevalence of *pfmdr1* and *pfcrt* molecular markers of antimalarial drug resistance across studies can be challenging due to the abundance and heterogeneity of studies. The purpose of this project was to develop a free online tool, which provided a standardized visualization of the published literature on molecular markers of ACT partner drug resistance, and a downloadable database. A global geospatial database of a selection of *pfmdr1* and *pfcrt* single nucleotide polymorphisms, and *pfmdr1* and *plasmepsin2* copy number variations associated with antimalarial drug resistance was developed, populated with data extracted from the literature published from 2001 to date. We conducted a literature review and designed a standardised method to extract data from publications, made critical decisions on visualisation, and created an online application for displaying the information within 6 months. We present the ACT Partner Drugs Molecular Surveyor database, which currently includes prevalence information linked to point locations, derived from over 570 sites in 76 different countries. The database currently includes results from over 90,000 samples from 453 publications. WWARN launched the ACT Partner Drugs Molecular Surveyor in March 2015 and it has attracted nearly 2,000 unique visitors since then (http://www.wwarn.org/tracking-resistance/act-partner-drug-molecular-surveyor). The database supporting the tool is fully accessible, providing users with a rich resource to explore and analyse. The informatics framework used for developing the tool can be easily adapted to other data, as demonstrated by the subsequent launch of our K13 artemisinin marker surveyor. Extracted data have also been used to build continuous maps for specific areas of the world where more intense marker prevalence mapping is taking place, also demonstrating the usefulness of a centralised standardised database. Further analyses of the ACT Molecular Surveyor dataset will be presented.

1709

EFFICACY OF ARTEMETHER-LUMEFANTRINE FOR THE TREATMENT OF UNCOMPLICATED *PLASMODIUM FALCIPARUM* MALARIA IN KLOUEKANMEY AND DJOUGOU, REPUBLIC OF BENIN

Adicath Adeothy[1], Augustin Kpemasse[1], Ernest Houngbo[1], Antoine Sianou[1], Ramani Saliou[2], Monica Patton[3], Fortune Dagnon[3], Eric Halsey[4], Samaly Santos Souza[4], Naomi Lucchi[4], Udhayakumar Venkatachalam[4], Alexandre Macedo de Oliveira[4], Alexis Tchevoede[5]

[1]National Malaria Control Program, Ministry of Health, Cotonou, Benin, [2]Medical Care Development International, Cotonou, Benin, [3]U.S. President's Malaria Initiative, U.S. Agency for International Development, Cotonou, Benin, [4]U.S. President's Malaria Initiative, U.S. Agency for International Development, Atlanta, GA, United States, [5]U.S. President's Malaria Initiative, Atlanta, GA, United States

In 2008, artemether-lumefantrine (AL) was introduced as first-line treatment for uncomplicated *Plasmodium falciparum* malaria in Benin. Following the World Health Organization recommendation to regularly monitor antimalarial efficacy, we conducted an efficacy study of AL for uncomplicated *P. falciparum* malaria in Klouekanmey and Djougou. Febrile patients 6-59 months old with *P. falciparum* monoinfection and 2,000-200,000 parasites/µl were treated with a 3-day course of AL. Clinical and parasitological response was monitored for 28 days. We differentiated recrudescence from reinfection using microsatellite genotyping and calculated uncorrected and corrected adequate clinical and parasitological response (ACPR) rates. We performed molecular analyses for PfK13 propeller and Pfmdr1 gene mutations, associated with artemisinin and lumefantrine resistance, respectively. In Klouekanmey, among the 115 patients who completed follow-up, 2 (1.7%) infections occurred on Days 21 and 25, yielding an uncorrected ACPR of 98.3% (95% confidence interval [CI]= 93.9-99.8). In Djougou, among 120 patients with complete follow-up, there was 1 (0.8%) early treatment failure (signs of severe malaria on Day 1) and 11 (9.2%) infections identified from Day 21 to 28, uncorrected ACPR of 90.0% (95% CI= 83.2-94.7). None of the recurrent infections in Klouekanmey and one in Djougou were classified as recrudescence by genotyping; microsatellite-corrected ACPRs of 100.0% (95% CI= 96.8-100.0) and 98.2% (95% CI= 93.6-99.8), respectively. No PfK13 gene mutations were observed at enrollment. Considering mutant and mixed (mutant and wild type) Pfmdr1 alleles, we observed prevalence of 11.2% and 58.9% for the 86Y and 184F mutations, respectively. AL remains efficacious for falciparum malaria in these two sites in Benin; however, we found a high frequency of the Pfmdr-1 Y184F mutant allele. Our study also revealed high incidence of recurrent infections in Djougou during the 28-day follow-up, highlighting the importance of considering clinical, parasitological, and molecular data together to adequately estimate treatment efficacy and drug resistance.

1710

USE OF DRUGS IN MANAGEMENT OF UNCOMPLICATED MALARIA IN RURAL, URBAN HEALTH CENTERS, AND REFERRAL HOSPITALS IN DEMOCRATIC REPUBLIC OF THE CONGO

Pierre-Michel Nsengi Ntamabyaliro[1], Didier Bomene Nzolo[1], Yves Ntamba Lula[1], Aline Biongo Engo[1], Gauthier Kahunu Mesia[1], Mariano Manzo Lusakibanza[1], Samuel Ma Miezi Mampunza[1], Jean-Marie Ntumba Kayembe[2], Eric Sompwe Mukomena[3], Didier Baneti Gasigwa[4], Gaston Lutete Tona[1]

[1]Clinical Pharmacology Unit, Faculty of Medicine, University of Kinshasa, Kinshasa, Democratic Republic of the Congo, [2]Department of Internal Medicine, Faculty of Medicine, University of Kinshasa, Kinshasa, Democratic Republic of the Congo, [3]Programme National de Lutte Contre le Paludisme, RDC, Kinshasa, Democratic Republic of the Congo, [4]Cellule D'appui et de Gestion, Ministère de la Santé Publique, RDC, Kinshasa, Democratic Republic of the Congo

The Democratic Republic of Congo (DRC) is still heavily affected by Malaria despite the adoption of the preventive measures and powerful drugs that have produced tremendous drop in malaria morbidity and mortality worldwide. Inappropriate use of these drugs may contribute to this underperformance. A retrospective review of patients' medical files containing a prescription of an antimalarial in a twelve months period was carried out in 2014 to assess the prescription of drugs in malaria. In each of the former 11 provinces of DRC, one Rural Health Center (RHC), one Urban Health Center (UHC) and one Referral Hospital (GRH) were selected and in each of them, 100 patients' files selected. In 2300 files (69.7%), uncomplicated malaria was the indication for antimalarial prescription. Descriptive analyses were performed. Antimalaria prescription was based on positive malaria tests in 51.5% of cases, without test in 37% and despite negative tests in 11%. RHC relied more on positive tests than GRH (62.7%vs 32.8%; p< .00001) and UHC (62.7% vs 56.7%; p= .015588). GRH prescribed antimalarials to patients with negative tests more than RHC (16.0% vs 4.4%, p<0.00001). The recommended drugs were more prescribed in RHC than GRH (67.3%vs 39;7%; p <0.00001). Quinine and the injectable artemether and alfa-beta arteether, were more prescribed in GRH where they represented 52% of prescriptions. Apart from antimalarials, patients received an average of 3.1 other drugs with no specified indication in 51% of cases. Antibiotics were prescribed to around 68% of patients in all settings. Anthelminthic (p<0.00001) and vitamins (p <0.00001) were significantly more prescribed in RHC. Anemia drugs, were prescribed more in RHC (p=.001848) and GRH (p<0.00001) than in UHC. The use of drugs in uncomplicated malaria is characterised by a low adherence to recommended policies and polypharmacy. Referral Hospitals adhere less whereas Rural health centers adhere more to national policy but prescribe more concomitant medications. Determinant of this inappropriate use of drug and the difference between health facilities need to be assessed.

1711

PLASMODIUM FALCIPARUM ARTEMISININ *IN VIVO* EFFICACY MONITORING AND MOLECULAR DRUG-RESISTANCE SURVEILLANCE IN A PRE-ELIMINATION SETTING IN SABAH, MALAYSIA

Matthew J. Grigg[1], Timothy William[2], Giri S. Rajahram[3], Rashidah Mohammad[4], Jenarun Jelip[5], Jayaram Menon[3], Kim A. Piera[1], Bridget E. Barber[1], Tsin W. Yeo[6], Nicholas M. Anstey[1]

[1]Menzies School of Health Research and Charles Darwin University, Darwin, Australia, [2]Jesselton Medical Centre, Kota Kinabalu, Malaysia, [3]Queen Elizabeth Hospital, Sabah Ministry of Health, Kota Kinabalu, Malaysia, [4]Sabah State Public Health Laboratory, Kota Kinabalu, Malaysia, [5]Ministry of Health, Kuala Lumpur, Malaysia, [6]Lee Kong Chian School of Medicine, Nanyang Technological University, Singapore, Singapore

Artemisinin derivatives are the WHO first-line treatment for severe and uncomplicated falciparum malaria. Spreading artemisinin drug-resistance threatens Southeast Asian malaria elimination goals. In Malaysia, the Ministry of Health is implementing drug response surveillance of artemisinin treatment efficacy, but there is only limited evaluation of *Plasmodium falciparum*-molecular artemisinin-resistance markers. This was a multi-centre open-label study conducted in three adjacent district hospitals in northwest Sabah, Malaysia, to assess clearance rates of *P. falciparum* parasitaemia in patients with acute uncomplicated malaria. Febrile non-pregnant patients with a positive *Pf*-HRP2 rapid diagnostic test, microscopic monoinfection with *P. falciparum* and a parasite count of 1,000-100,000/µL were enrolled, with *Plasmodium* species confirmed by PCR. Patients received oral artesunate alone (total target dose 12mg/kg) for 3 days, followed by oral mefloquine. Blood slides were taken 6-hourly to calculate microscopic parasite clearance. Molecular surveillance of 20 SNPs in the *P. falciparum* K13 propeller domain associated with artemisinin-resistance were evaluated by PCR, including in additional patients with falciparum malaria enrolled in a prospective tertiary-referral hospital study for western Sabah. From 2012-15, 59 patients with falciparum malaria were enrolled in the artemisinin *in vivo* efficacy study. Median age was 21 years (IQR 12-31; range 3-62), with 15 (25%) being children ≤12 years. Median parasite count at presentation was 9,074/µL. The median parasite clearance time was 24 hours (IQR 18-42; range 6-72), and median time to 50% parasite clearance was 4.2 hours. All patients were microscopy-negative for parasites by 72 hours. For the molecular surveillance study, a total of 264 patients with falciparum malaria from western Sabah were evaluated for K13 drug-resistance markers, with all SNPs found to be wild-type. In conclusion, artemisinin derivatives remain highly efficacious for the treatment of falciparum malaria in Sabah, Malaysia, with no K13 drug-resistance markers detected.

1712

EVALUATION OF ACCURACY OF MAGNETO-OPTICAL METHOD FOR THE DETECTION OF MALARIA PARASITES

Prasanna Jagannathan[1], Harriet Adrama[2], Richard Kajubi[2], Tamara Clark[3], Grant Dorsey[3], Moses Kamya[4], Bryan Greenhouse[3], Priyaleela Thota[5]

[1]Stanford University, Palo Alto, CA, United States, [2]Infectious Diseases Research Collaboration (IDRC), Tororo, Uganda, [3]University of California, San Francisco (UCSF), San Francisco, CA, United States, [4]Makerere University School of Medicine, Kampala, Uganda, [5]Hemex Health, Inc., Portland, OR, United States

Malaria is a global public health problem and is prevalent in tropical and subtropical regions. Laboratory techniques to confirm clinical suspicion of malaria have traditionally relied on microscopy and more recently on rapid diagnostic tests (RDTs). Although inexpensive, microscopy is labor intensive and requires skilled personnel. RDTS are relatively easy to perform and do not need specialized facilities. However, accuracy of RDTs is of concern and most cannot reliably detect parasitemia lower than 100-200 parasites/µL. There is an acute need for improved malaria diagnostics that are not only cost-effective but also rapid and highly accurate. Our study evaluated a rapid (<1 minute) malaria detection device called Magneto-Optical Detection (MOD). The principle is based on using a magnetic field to detect hemozoin, a by-product of parasite digestion of hemoglobin. Upon being placed in an intense magnetic field, the iron-bearing hemozoin crystals align within the field, thereby affecting the opacity of the sample. The parasite level is determined by analyzing the resulting signal from a polarized light source passing through the test sample with and without the magnetic field. We are evaluating the diagnostic accuracy of the MOD as a point-of-care diagnostic for malaria, using samples collected from children enrolled in a longitudinal birth cohort study in Busia, Uganda, a high transmission setting. Study participants are ages 6 months to 1 year and have both passive and active (monthly) surveillance for malaria parasites. MOD results are being compared to microscopy, a standard case-management RDT (CareStart Pf HRP-2), and qPCR as a reference standard. Total enrollment is 300 children. Sixty children were tested until now, of whom 25 were tested at the time of acute febrile illness and 35 were tested at a routine asymptomatic visit. Preliminary results show the MOD to have similar sensitivity and much higher specificity than RDTs, and turn-around-time was significantly faster at one-minute than either microscopy or RDTs. Final results after completion of microscopy and qPCR will be presented at the conference.

SHERLOCKING MALARIA: A SENSITIVE, ISOTHERMAL, NUCLEIC ACID-BASED DIAGNOSTIC CAPABLE OF DISTINGUISHING *PLASMODIUM* SPECIES

Clark H. Cunningham, Jonathan J. Juliano, Jonathan B. Parr

The University of North Carolina at Chapel Hill, Chapel Hill, NC, United States

Antigen-based malaria rapid diagnostic tests (RDTs) are inexpensive and convenient for field use, but lack the sensitivity and specificity of nucleic acid detection methods. We sought to develop a sensitive diagnostic that combines affordability, high sensitivity, and the ability to distinguish *Plasmodium* species by adapting the Specific High-Sensitivity Enzymatic Reporter UnLOCKing (SHERLOCK) method developed by Gootenberg et. al. (*Science* 2017) to detect *Plasmodium falciparum* and *Plasmodium vivax* at levels comparable to current PCR-based assays. This method combines isothermal recombinase-polymerase amplification (RPA), *in vitro* transcription, CRISPR RNA (crRNA) base-pairing, and collateral cleavage of fluorescent RNA reporters by LwCas13a to detect DNA or RNA targets. Previous SHERLOCK assays have achieved sensitivity to attomolar concentrations of nucleic acid, specificity to the single nucleotide level, and rapid read-out times of less than two hours. SHERLOCK has the additional advantage of being less resource-intensive than PCR, with the reaction being run at a constant temperature and read with a simple plate reader. Future directions include adapting our assay for field-deployable lyophilized and lateral flow platforms, as has been previously accomplished with SHERLOCK assays for other pathogens, as well as testing clinical isolates and developing crRNAs capable of detecting other malaria species and drug resistance alleles.

1714

TRACKING HEMOZOIN LEVELS OVER TIME IN SYNCHRONOUS CULTURES OF *PLASMODIUM FALCIPARUM* USING MAGNETO-OPTICAL DETECTION (MOD)

Brian Grimberg[1], Tyler Witte[2], Allison Watts[2], D'Arbra Blankenship[1]

[1]Case Western Reserve University, Cleveland, OH, United States, [2]Hemex Health, Inc, Portland, OR, United States

Hemozoin, a by-product of malaria digestion of haemoglobin, is proposed as a biomarker for malaria. An open question is the time point after invasion when hemozoin becomes detectable. Previous studies have failed

to detect hemozoin in early ring stage parasites. This study evaluates the ability of magneto-optical detection (MOD) to detect parasites throughout a 48-hour incubation. To perform this test, a sample of 3D7 lab strain of *P. falciparum* was synchronized, washed (removing all exogenous hemozoin), and diluted to 5000 parasites/uL and 100 parasites/uL. The MOD device detected hemozoin in these 100% tiny ring stage parasites even before incubation. Then the culture was incubated at 37oC for 48 hours and sampled every 2 hours. A steady increase in hemozoin content in both the low and high parasitemias was observed. This study shows that early ring stage parasites do in fact have quantifiable levels of hemozoin that can be detected by MOD. The presence of hemozoin in all parasite stages demonstrates the usefulness of hemozoin as a biomarker. Future work will repeat the study for other species of malaria.

1715

EVALUATION OF A SINGLE SCREEN AND TREAT STRATEGY FOR PREGNANT WOMEN AT SELECT HEALTH FACILITIES IN LINDI REGION, TANZANIA

Chonge A. Kitojo[1], Emmanuel Kigadye[2], Joseph Mugasa[3], Erik Reaves[4], George Greer[1], Julie Gutman[5], Deus Ishengoma[6]

[1]U.S. Agency for International Development, Dar es salaam, United Republic of Tanzania, [2]The Open University of Tanzania, Dar es salaam, United Republic of Tanzania, [3]U.S. Agency for International Development Boresha Afya, Dar es salaam, United Republic of Tanzania, [4]Malaria Branch, Division of Parasitic Diseases and Malaria, Centers for Disease Control and Prevention and US President's Malaria Initiative, Dar es salaam, United Republic of Tanzania, [5]Malaria Branch, Division of Parasitic Diseases and Malaria, Centers for Disease Control and Prevention, Atlanta, GA, United States, [6]National Institute for Medical Research, Tanga Centre, Tanga, United Republic of Tanzania

Since 2014, Tanzania has been implementing a policy of single screen and treat (SST) of all pregnant women using HRP-2 based malaria rapid diagnostic tests (mRDT) at first antenatal care (ANC) visit, together with intermittent preventive treatment in pregnant women (IPTp). However, there is paucity of data to show its effectiveness in identifying women with malaria parasites and reducing the adverse effects of malaria in pregnancy (MiP). We evaluated the proportions of asymptomatic and symptomatic women identified by SST to determine its potential utility in reducing adverse effects of MiP. A cross-sectional study was conducted at 8 heath centres selected for high numbers of ANC attendees in two randomly selected districts of Kilwa and Lindi in Lindi Region, Tanzania. Pregnant women attending their first ANC visits were enrolled and retrospective data collected included gestation age, history of fever, mRDT results and treatment provided. From October 2017 to January 2018, 769 pregnant women were tested for malaria (20% in 1st trimester) and 106 (13.8%) had mRDT positive results. The positivity rates at the HF ranged from 0 - 29%; one HF had no asymtomatic women or malaria cases, three had positivity rates <4% (low prevalence), the other four had positivity rates ranging from 17 - 29% (moderate prevalence). Fifty-nine (8%) women reported fever within the past 48 hours; all symptomatic women had positive mRDT results. Forty-seven (6%) women with positive results were asymptomatic. All women with positive mRDTs and none of those with negative mRDTs were treated. In the HFs with low prevalence, only one malaria case was asymptomatic (13%, 1/8), while in those with moderate prevalence the proportion of asymptomatic cases was 47% (46/98), and ranged from 0 - 90%. While in low prevalence areas, SST detected primarily symptomatic women, who should have been identified and treated even in absence of SST policy, in moderate prevalence settings, SST detected a high proportion of asymptomatic women who would have otherwise gone undetected. In this high SP resistance setting, an evaluation of the impact of SST on birth outcomes may be warranted.

1716

MODELING HRP2 DYNAMICS AND THE IMPLICATIONS FOR A NEW ULTRA-SENSITIVE RAPID DIAGNOSTIC TEST (U-RDT)

Ruiyun Li[1], Azra Ghani[1], Patrick Walker[1], Hannah Slater[1], Gonzalo J. Domingo[2], Smita Das[2]

[1]Imperial College London, London, United Kingdom, [2]Diagnostics Program, PATH, Seattle, WA, United States

Of the rapid diagnostic tests (RDTs) routinely utilized to diagnose symptomatic *Plasmodium falciparum* malaria, the most frequently used detect HRP-2 antigen expressed by the parasites. In 2017 a new ultra-sensitive rapid diagnostic (U-RDT) was released with higher sensitivity at detecting HRP-2. The utility of this new diagnostic for detecting symptomatic and asymptomatic infections is currently being explored in field studies. Although the presence of the parasite and HRP-2 are correlated, HRP-2 typically persists for weeks after an infection has been cleared. We therefore sought to characterize HRP2 dynamics following treatment in order to quantify the likely relationship between malaria infection status and positivity by conventional RDTs and U-RDTs. A bi-phasic exponential decay model was fitted to repeated measures of HRP-2 concentration from non-immune treated individuals. We find that there is an initial rapid decay in the first 1.5 days followed by a subsequent second slower clearance. Combining this with data from the same individuals on their detectability by different diagnostics over time, we estimate that individuals will remain positive for approximately twice as long after treatment by the U-RDT compared to a conventional (HRP2) RDT. Cross-sectional data were then used to estimate the proportion of the infected population (using PCR positivity as the gold standard) that would be detected using the new U-RDT and to estimate the probability of detection by U-RDT and RDT for a given parasite density. For example, we estimate that for a parasite density of 100 parasites/ul, an individual has a 97% probability of being detected using the U-RDT but only 62% by a conventional RDT. Quantifying how the increased sensitivity of the U-RDT corresponds to detecting individuals (with differing levels of parasitaemia and HRP-2) in endemic populations is a vital first step in understanding the utility of the U-RDT in a range of use scenarios such as for surveillance or testing individuals prior to mass treatment interventions.

PERFORMANCE OF A NEW MULTIPLEX FEVER PATHOGEN RAPID TEST TO DETECT MALARIA WHEN USED BY HEALTH WORKERS IN PERU AND NIGERIA

Sandra Incardona[1], Katherine Torres[2], Wellington Oyibo[3], Stefano Ongarello[1], Aurélien Macé[1], Freddy Alava[2], Sabine Dittrich[1], Javan Esfandari[4], Dionicia Gamboa[2], Angelo Gunasekera[4], Uche Igbasi[3], Paul Lambotte[4], Oladosu Oladipo[3], Louise Sigismondi[4], Ifeoma Udenze[3], Iveth J. Gonzalez[1], Cassandra Kelly[1], Bill Rodriguez[1]

[1]FIND, Geneva, Switzerland, [2]Laboratorios de Investigación y Desarollo, Facultad de Ciencias y Filosofía, Universidad Peruana Cayetano Heredia, Lima, Peru, [3]ANDI Centre of Excellence for Malaria Diagnosis, College of Medicine, University of Lagos, Lagos, Nigeria, [4]Chembio Diagnostics Systems Inc., New York, NY, United States

To manage fever cases at the point of care (POC), new multiplexed rapid tests (RDTs) are needed that can identify non-malaria pathogens when malaria RDT results are negative. This is critically important for outbreak pathogens like Ebola. The ideal test would detect all relevant pathogens in each geography, including malaria, a major cause of fever globally. A new multiplexed RDT, the DPP® Fever Panel Antigen System (Chembio, USA), is designed to detect seven African pathogens (Ebola, Lassa, Marburg, Chikungunya, Dengue, Zika, and malaria) in <15 minutes. To evaluate the malaria component (HRP2 and pLDH for *P. falciparum* and any *Plasmodium* species, respectively) in comparison with microscopy and real-time PCR, FIND conducted field studies between March and October 2017, in 3,200 and 1,300 self-presenting febrile patients in Peru and Nigeria, respectively. Blood samples were collected for microscopy and PCR amplification

of *Plasmodium* mtDNA. Compared to microscopy, DPP® results from fingerprick blood in Nigeria showed good performance of the HRP2 test line to detect *Plasmodium* infections with 98.7% sensitivity [CI95%: 97.2-100.0%] and 88.6% specificity [CI95%: 86.5-90.6%]. The pLDH test line performance to detect any species was lower (70.8% sensitivity [CI95%: 68.0-73.6%] and 91.8% specificity [CI95%: 90.9-92.8%]), in Peru and Nigeria. These results compare favorably to the performance of high quality malaria RDTs used for on-site case management. In comparison to the SD Bioline Malaria Ag P.f/Pan (Alere, USA) in Nigeria, DPP® performance was 99.3% sensitivity [CI95%: 98.4-100.0%] and 96.4% specificity [CI95%: 95.2-97.6%] on the HRP2 test line. In Peru, DPP® performance was 71.2% sensitivity [CI95%: 68.1-74.4%] and 96.2% specificity [CI95%: 95.4-97.0%] on the pLDH test line, compared to the *Carestart*™ pLDH (Pf/PAN) RDT (Access Bio, USA). In sum, the DPP® Fever Panel Antigen System shows good performance for malaria detection in POC settings, comparable to available malaria RDTs. These studies constitute one step toward regulatory approval and the commercial availability of this new POC test for fever-causing infections in Africa.

DETECTION OF *PLASMODIUM* INFECTION UTILIZING DRIED BLOOD SPOTS AND SIMPLIFIED MICROCAPILLARY CYTOMETRY

Julie Clor[1], Kamala Tyagarajan[1], Mary Otto[2], John McDonald[2], James Mulry[3], Beatrice Greco[4]

[1]MilliporeSigma, Hayward, CA, United States, [2]MilliporeSigma, St. Charles, MO, United States, [3]Merck Global Health Institute, Billerica, MA, United States, [4]Merck Global Health Unit, Merck Biopharmaceutical Research & Development, Coinsins, Switzerland

Sample collection, storage and analysis often prove to be challenging for epidemiological studies and malarial disease monitoring in constrained settings. One approach to circumvent this is collecting blood via finger stick/venous draw spotting onto filter paper in the form of dried blood spots (DBS). The dried blood spots are often stored at ambient temperature/refrigerated/frozen conditions and allow for the easy transportation of a large number of samples to study sites for further analysis. These methods have been frequently applied to PCR/molecular detection but less often to multiple malarial antigens for compatibility with assays. Here we present results to detect *Plasmodium* infections after extraction from DBS and analysis on an affordable miniaturized flow cytometry platform, the Muse® Cell Analyzer utilizing a recently developed bead multiplexed bead based immunoassay for multiple *Plasmodium* antigens. This bead based assay allows for a highly sensitive, multiplexed distinction of *Plasmodium falciparum*, *Plasmodium vivax* and mixed infections. Utilizing blood spotted and stored on filter paper, stored at either room temperature or frozen , we were able to successfully detect both HRP2 and LDH antigens for *falciparum* based infection and LDH antigen for *vivax* based infection or all above antigens for mixed infection for positive samples across a broad range of parasitemia. Clear distinction was possible for positive, negative and mixed samples in the limited sample set studied. Data from longitudinal studies of storage of DBS and application to wider sample set will also be presented along with dilution of samples to determining the lower level of detection of the assay with dried blood spots. The combination of the Muse *P.f/P.v.* bead assay along with dried blood spot extraction and paired with simplified analysis on Muse® Cell Analyzer can provide comprehensive and sensitive solutions from collection, storage to analysis in an easy to use format that would be usable in diverse settings.

1719

TOWARDS A GLOBAL MAP OF *PLASMODIUM FALCIPARUM HRP2* DELETION FOR THE SELECTION OF OPTIMAL RDTS FOR MALARIA DIAGNOSIS

Cristian Koepfli, Guiyun Yan

University of California Irvine, Irvine, CA, United States

Rapid diagnostic tests (RDTs) are an indispensable tool for diagnosis of clinical malaria and screening of asymptomatic carriers. The most sensitive RDTs for *P. falciparum* rely on detection of the HRP2 protein, but deletion of the *hrp2*-gene results in false-negative results. The extent of *hrp2*-deletion is not known in many countries where RDTs are used. It is also unclear whether the use of HRP2-based RDTs is a selective force strong enough to result in an increase of *hrp2*-negative parasites over time. Molecular monitoring of the extent of *hrp2* deletion is crucial to select the optimal diagnostic tools and to understand the spread of *hrp2*-negative parasites, but laboratory testing has been challenging. We have developed a highly-sensitive, high throughput method to screen for *hrp2* and *hrp3* deletion, based on droplet digital PCR (ddPCR). Our method is able to detect mixed infections with wild-type and *hrp2*-negative parasites. Analysis of samples from East Africa and other sites shows substantial differences between sites. Use of screening methods that cannot detect mixed infections of wild-type and *hrp2*-negative clones in regions with frequent multiple clone infection underestimates the true frequency of *hrp2*-deletion. In conclusion, screening by ddPCR greatly facilitates molecular surveillance of *hrp2* and *hrp3* deletion, and can inform malaria control programs on the optimal selection of diagnostic tests.

1720

MODELLING THE IMPACT OF AN ULTRA-SENSITIVE *PLASMODIUM FALCIPARUM* RAPID DIAGNOSTIC TEST (U-RDT): DETECTING ASYMPTOMATIC INFECTIONS AND THE POTENTIAL FOR OVERTREATMENT

Hannah C. Slater, Ruiyun Li, Patrick G. Walker, Azra Ghani

Imperial College, London, United Kingdom

In 2017 a new ultra-sensitive *Plasmodium falciparum* rapid diagnostic test (U-RDT) with a limit of detection ten times lower than current RDTs was released. To better understand the potential utility of this novel tool, we used modelling to explore its value in different use case scenarios. We extended an existing malaria transmission model using data on the U-RDT to estimate how this 10x increased sensitivity translates to the proportion of the population and proportion of the infectious reservoir that would be detected in different transmission settings. In high transmission settings, we predict that this test would detect 95% of the infectious reservoir (compared to 55% with a conventional RDT). We then use the model to explore the impact of two asymptomatic infection detection interventions: i) active infection detection using the U-RDT in the households of symptomatic cases, where a combination of DHS and trial data are used to estimate the increased probability of infection in a household with symptomatic infection ii) Mass Screen and Treat, where preliminary results indicate that this diagnostic would reduce the number of years the intervention would be needed to interrupt transmission, for example, in a setting with an EIR of 1, 3 years of MSAT are needed to interrupt transmission compared to 8 years with a conventional RDT. We also consider the potential for overtreatment if the U-RDT is used for diagnosing symptomatic malaria. Individuals that have asymptomatic malaria infection or have recently been successfully treated for a malaria infection are likely to have positive HRP-2 concentrations (the antigen detected by the U-RDT) - if these individuals seek treatment for a non-malarial fever, there is an increased probability that they will be misdiagnosed as having malaria as their primary cause of fever. Data from challenge studies to estimate HRP-2 clearance after treatment and DHS data to estimate the prevalence of non-malarial fevers is used to estimate

the additional number of antimalarial doses that will be mis-administered if the U-RDT is used to diagnose symptomatic malaria in a range of transmission settings.

1721

MOLECULAR DIAGNOSIS FOR SURVEILLANCE OF ASYMPTOMATIC MALARIA IN THE PERUVIAN AMAZON

Viviana Pinedo-Cancino[1], Rafael Saavedra-Langer[1], Katty M. Arista[1], Maritza Calderon[2], Andres G. Lescano[3], Lastenia Ruiz[1]

[1]Laboratorio de Productos Naturales Antiparasitarios de la Amazonia, Centro de Investigación de Recursos Naturales de la Amazonia, Universidad Nacional de la Amazonia Peruana, Iquitos, Peru, [2]Laboratorio de Investigación en Enfermedades Infecciosas, Universidad Peruana Cayetano Heredia, Lima, Peru, [3]Facultad de Salud Pública y Administración, Universidad Peruana Cayetano Heredia, Lima, Peru

Malaria in the Peruvian Amazon is an important public health problem that seeks to be reduced from this region in 2021 with the new "Malaria Zero Plan". There is a great need to know the best diagnostic strategies. We evaluated the diagnostic performance of the hemi-nested, multiplex polymerase chain reaction (PCR) comparing two different DNA extraction methods, to nested-PCR alongside Giemsa microscopy. One hundred and sixty-six participants from the community of Zungarococha (Iquitos, Peru) were recruited during cross-sectional surveys and screened for *Plasmodium* parasites by hemi-nested-PCR, nested-PCR assays and Giemsa microscopy. The isolation of DNA from blood was carried out using the DNeasy Blood and Tissue kits (QIAGEN) and the simple extraction buffer (400mM NaCl, 40 mM Tris pH 6.5, 0.4% SDS). *Plasmodium vivax* cases confirmed by Giemsa microscopy, nested-PCR, hemi-nested-PCR with the simple extraction buffer and hemi-nested-PCR with QIAGEN were 6.6%, 28.3%, 18.1% and 36.8%; and for *P. falciparum* cases were 3%, 4.2%, 1.3% and 3.6%, respectively. Only the hemi-nested-PCR with QIAGEN found one mixed infection (0.6%). Considering hemi-nested-PCR with QIAGEN as gold standard, microscopy was able to detect 17.7% and 57.1% of any Pv and Pf infection, respectively; while nested-PCR detected 69.4% and 28.6%; and hemi-nested-PCR with the simple extraction buffer 47.4% and 71.4% of the Pv and Pf cases, respectively. Both molecular methods showed higher specificity than 96%. Low density submicroscopic asymptomatic *Plasmodium* carriage is common in Zungarococha and microscopy diagnosis is less sensitive to detect human reservoir with low levels of parasite densities. Our data confirms that molecular methods should be used to identify parasites carriers to guide mass screening of malaria control and elimination programs. The easy and low cost of the simple buffer extraction should be considered for its application in laboratories of low resources.

1722

EVALUATION OF A MULTIPLEXED PLASMODIUM LACTATE DEHYDROGENASE BASED ASSAY USING SIMPLIFIED CYTOMETRY ON MUSE® CELL ANALYZER

Rekha Kannan[1], Julie Clor[1], James Mulry[2], Beatrice Greco[3], **Kamala Tyagarajan**[1]

[1]Millipore Sigma, Hayward, CA, United States, [2]Merck Global Health Institute, Darmstadt, Germany, [3]Merck Global Health Institute, Merck Biopharmaceutical, Coinsins, Switzerland

Malaria remains one of the leading cause of mortality rate at global level, prompting the need to develop effective and sensitive research and diagnostic strategies. Three antigens have been typically used for multiple tests in particular RDT's: *Plasmodium* Histidine Rich Protein 2 (HRP2), lactate dehydrogenase (LDH) and aldolase. However, RDT's are liable to several challenges and difficulties, including inadequate sensitivity, specificity and false-positive/negative outcomes. Recent studies have reported *P.f.* HRP2/3 gene deletions resulting in false negative results while the delayed clearance of the HRP2 antigen is not reflective of current infection. Due to these implications, there is current need for alternative antigens with high sensitivity performance as HRP2. We recently demonstrated the utility of the touch screen based cytometer, the Muse® Cell Analyzer and bead based assays for sensitive and multiplexed malarial antigen detection. In this study, we further expanded the approach by evaluating a multiplexed assay for detection of *P.f.* LDH, *P.v*. LDH and Pan LDH in parallel . The addition of the pan LDH marker allows for potential capability to detect the four major *Plasmodium* species. In data obtained on frozen blood samples, the assay shows capability to detect and identify *P. falciparum* and *P. vivax* LDH as well as *P. malariae* samples. Limitation in sample availability have not yet allowed for testing in *P. ovale* samples. Data from frozen blood samples across a range of parasitemia demonstrates good performance with the assay. Performance data across a wider range of parasitemia will also be presented. The multi-LDH assay has also shown good specificity for LDH type without cross reactivity. Dilution studies demonstrate low sensitivity of detection in the order of 5 parasites/uL for *falciparum* and *vivax* antigens. The availability of a simplified YES/NO robust LDH based assay on Muse® Cell Analyzer that can detect expanded plasmodium species provides a powerful tool for malaria applications in a sensitive easy to use format.

1723

CROSS REACTION OF ANTI-*PLASMODIUM FALCIPARUM* PLDH ANTIBODIES WITH *PLASMODIUM MALARIAE* PLDH USING THE RAPID DIAGNOSTIC TEST SD BIOLINE MALARIA PF/PF/PV (05FK123)

Silvia M. Di Santi, Giselle F. Lima, Juliana Inoue, Maria J. Costa-Nascimento, Maria L. Farinas, Maria Carmen A. Sanchez

São Paulo University, São Paulo, Brazil

Diagnosis of malaria is based on thick blood smear, still considered the reference test; however, its sensitivity depends on the expertise of the examiner. Rapid diagnostic tests (RDTs) dispenses expertise and can be performed at the point of care. In endemic areas, the laboratories lack facilities and in non endemic areas it is very difficult to maintain well trained personal. Molecular protocols can only be conducted in reference centers, leading to the search for accurate RDTs to be used in the routine, avoiding indiscriminate use of antimalarials. We describe a cross reaction of anti-*Plasmodium falciparum* pLDH antibodies with *P. malariae* pLDH using the RDT SD Bioline Malaria Pf/Pf/Pv (05FK123). Samples from positive patients by thick blood smear and nested PCR were tested: 10 positives for *P. falciparum*, 10 for *P. vivax* and 9 for *P. malariae*. The SD Bioline Malaria Ag Pf/Pf/Pv test is defined as a rapid, qualitative and differential test for the detection of histidine-rich protein II (HRP-II) antigen of *P. falciparum* (band T1), pLDH of *P. falciparum* (band T2) and pLDH of *P. vivax* (band T3) in human whole blood. Tests were conducted according to the manufacturer instructions. Among *P. falciparum* isolates, sensitivity was 100.0% (95% CI 72.2-100.0) considering both antigens and 90.0% (95% CI 59.6-100.0). For *P. vivax*, sensitivity was 100.0% (95% CI 72.2-100.0) for pLDH. Among *P. malariae* isolates, 88.9% (95% CI 56.5-98.0) cross reacted with anti-*P. falciparum* pLDH antibodies. Some advantages attributed to the SD Bioline Malaria Pf/Pf/Pv are the differential detection of *P. falciparum* and *P. vivax*, usefulness in regions where both species occur, ability of identifying false positives by HRP-II after treatment and usefulness in regions where HRP-II gene deletion is suspected. The cross reactions observed here point out to the need for developing of more specific TDRs, avoiding the misdiagnosis of *Plasmodium* species and the unsuitable treatment especially in resource-limited settings.

1724

REFINING OPERATIONAL STRATEGIES TO DETECT IMPORTATION AND ELIMINATE RESIDUAL *FOCI* OF MALARIA TRANSMISSION IN KWAZULU-NATAL, SOUTH AFRICA

Jaishree Raman[1], Laura Gast[2], Basil Brooke[1], Rajendra Maharaj[3], Givemore Munhenga[1], Power Tshikae[1], Vishan Lakan[3], Ryleen Balawanth[2], Craig Davies[2], Lindi Sangweni[4], Moses Mkhabela[4], Nompumelelo Zondo[4], Zuziwe Nyawo[4], Sipho Msimang[5], Rebecca Graffy[2], Bheki Qwabe[4], Devanand P. Moonasar[6]

[1]National Institute for Communicable Diseases, Johannesburg, South Africa, [2]Clinton Health Access Initiative, Pretoria, South Africa, [3]Medical Research Council, Durban, South Africa, [4]KwaZulu-Natal Provincial Department of Health, Jozini, South Africa, [5]KwaZulu-Natal Provincial Department of Health, Pietermaritzburg, South Africa, [6]National Department of Health; University of Pretoria, Pretoria, South Africa

The South African province of KwaZulu-Natal (KZN) is extremely close to malaria elimination, with only 106 local cases in 2017, down from over 22,000 in the year 2000. A core intervention used by the KZN Malaria Control Program has been a multi-pronged approach to case detection, namely passive case detection, reactive case detection in response to local cases, proactive case detection in communities with a history of malaria transmission, and proactive case detection in border areas and amongst at-risk highly mobile populations. To reach elimination, the program conducted a survey between February and March 2018 aimed at (1) investigating potential drivers of transmission that may have been missed through other program activities, such as a potential for an asymptomatic reservoir, (2) investigating the potential need for interventions that relate to travel, travel pathways, and imported malaria, and (3) investigating the operational utility of a highly-sensitive RDT to identify a potential asymptomatic reservoir. To address these aims, the survey was conducted both at the household-level in communities as well as at known gathering places along borders, including border markets and taxi stands. Preliminary findings from this survey indicate that border market locations are a key location to target for active case detection (ACD). Based on these preliminary results, the proactive case detection in border markets and taxi stands yielded a positivity rate of 7% (65/890), compared to 0.19% (4/2,101) in at-risk communities, which relates closely with the rate of 0.012% (12/100,153) through routine ACD in 2016. In the survey, 95% of cases discovered (65 of 69) in the survey were at those border markets and taxi stands versus in the community. Of those 5% of cases discovered in the community (4 of 49), all had recent travel history to malaria endemic areas of Mozambique. All individuals who tested positive via the highly sensitive RDT tested positive by standard RDT. This analysis will provide detail about lessons learnt during ACD as the province nears elimination, and to inform its ACD strategy moving forward.

1725

IDENTIFICATION OF THE ZOONOTIC MALARIA SPECIES *PLASMODIUM KNOWLESI* IN ACEH PROVINCE, INDONESIA: DIAGNOSTIC SENSITIVITY, TRUE BURDEN AND IMPLICATIONS FOR ELIMINATION

Farah N. Coutrier[1], Martha G. Silaen[1], Iska Zarlinda[1], Chris Cotter[2], Iqbal RF Elyazar[3], Lenny L. Ekawati[3], Bimandra A. Djaafara[3], Cut Maneh[4], Abdul Fatah[5], Dita Ramadona[6], Maria E. Sumiwi[7], Ferdinand D. Laihad[7], Elvieda Sariwati[8], Adam Bennett[2], Jennifer L. Smith[2], Rintis Noviyanti[1]

[1]Eijkman Institute for Molecular Biology, Jakarta, Indonesia, [2]Malaria Elimination Initiative, Global Health Group, University of California San Francisco, San Francisco, CA, United States, [3]Eijkman-Oxford Clinical Research Unit, Jakarta, Indonesia, [4]Unit Pelaksana Teknis Dinas Laboratorium Kesehatan Daerah, Banda Aceh, Indonesia, [5]Aceh Provincial Health Office, Banda Aceh, Indonesia, [6]UNICEF, Banda Aceh, Indonesia, [7]UNICEF, Jakarta, Indonesia, [8]National Malaria Control Program, Ministry of Health, Jakarta, Indonesia

Plasmodium knowlesi is the cause of zoonotic human malaria in southeast Asia and its presence was reported for the first time in Aceh Province, Indonesia, in 2016. Due to morphological similarities with the three other human malaria species historically dominating transmission in this area (*P. falciparum, P. vivax* and *P. malariae*), it is possible that this species is routinely misidentified and its burden underestimated. Detailed evidence on the true burden of *P. knowlesi* infection relative to other species is crucial to provide appropriate case management guidelines and plan elimination strategies. This study used molecular methods to detect and identify *Plasmodium* species amongst all microscopy-positive malaria cases and a group of microscopy-negative controls presenting to health facilities or identified during reactive screening activities in two districts (Aceh Besar and Aceh Jaya Districts) in Aceh Province, from April 2017 and ongoing through September 2018. Malaria species identification methods by microscopy and loop mediated isothermal amplification (LAMP), were confirmed by nested PCR targeting the 18 small sub-unit ribosomal RNA (18S rRNA). The species-specific diagnostic sensitivity and specificity of microscopy and LAMP will be calculated using nested PCR as a gold standard. To date, nested PCR results confirmed that more than 70% of malaria cases were infected with *P. knowlesi*. Our finding suggests that this zoonotic infection is the most common cause of indigenous malaria in this area and commonly misidentified, which has important implications for diagnostic testing and case management.

THE PREVALENCE AND DISTRIBUTION OF *PLASMODIUM* SPECIES AMONG CHILDREN AT MALABO REGIONAL HOSPITAL ON BIOKO ISLAND, EQUATORIAL GUINEA

Leonor Ada Okenve[1], Consuelo Ndong Avomo[1], Gninoussa Akadiri[2], Matilde Riloha Rivas[1], Ramona Mba Andeme[1], Mariluz Mangue[1], Mariluz Mangue[1], Godwin Fuseini[2], Wonder Philip Phiri[2], Carlos Cortes Falla[2], Guillermo Garcia[3]

[1]Ministry of Health and Social Welfare, Malabo, Equatorial Guinea, [2]Medical Care Development International, Malabo, Equatorial Guinea, [3]Medical Care Development International, Silver Spring, MD, United States

According to the World Health Organization (WHO), *Plasmodium falciparum* (Pf) infections account for about 99% of the total malaria cases in Africa. Thus antimalarial drugs and vaccines are mostly developed to target Pf infections. However, most malaria-endemic countries are increasingly recording mixed *Plasmodium* infections involving two or more of the species. Artemisinin-based combination therapies (ACTs), which are effective against blood stage infections, are recommended by WHO for the treatment of uncomplicated malaria caused by Pf. Relapses of *Plasmodium vivax* (Pv) and Plasmodium ovale (Po) blood stage can occur months after treatment of primary blood stage infections. Interactions of mixed *Plasmodium* species infections can influence the severity of the disease. Understanding the extent of mixed Plasmodium infections and species distribution on Bioko Island is important for the ongoing malaria vaccine trials in Equatorial Guinea. A total of 237 confirmed malaria cases were examined by microscopy to determine species-specific parasitemia and the prevalence of mixed infection at the Malabo Regional Hospital among children between one to 14 years old. Three species of *Plasmodium* were identified, *P. falciparum, P. malariae, and P. ovale*. Infections with *P. falciparum* alone accounted for 84.8% of the total cases, and that of *P. malariae* alone was 1.7%. Mixed infection of *P. falciparum* with *P. malariae* was 13.1%, while mixed infection of *P. malariae* with *P. ovale* accounted for 0.4%. Malaria vaccines and control strategies targeting only the dominant species could end up replacing the less dominant species. It is therefore important to establish the prevalence and the distribution of the different species of human Plasmodium parasites in control programs.

1727

THE HEMATOLOGICAL RESPONSE FOLLOWING CHLOROQUINE TREATMENT OF *PLASMODIUM VIVAX* WITH OR WITHOUT PRIMAQUINE: A POOLED ANALYSIS OF INDIVIDUAL PATIENT DATA

Robert J. Commons[1], on behalf of the WWARN Vivax Study Group[2]

[1]Menzies School of Health Research, Darwin, Australia, [2]WorldWide Antimalarial Resistance Network (WWARN), Oxford, United Kingdom

Primaquine (PQ) is the only widely available treatment for the prevention of *Plasmodium vivax* relapse. Malaria causes anaemia that can be compounded by primaquine-induced haemolysis, particularly in glucose-6-phosphate-dehydrogenase (G6PD) deficient individuals. The aim of this study was to determine the haematological response following *P. vivax* malaria and the attributable haemolysis induced by primaquine. We conducted a systematic review to identify all prospective *P. vivax* therapeutic clinical trials published between January 2000 and March 2017. Individual patient data were pooled using standardised methodology and the haematological response estimated using a linear mixed effects model with non-linear terms, controlling for confounding factors. In total, 3,421 patients from 29 studies were included in the analysis, 99.2% (3,393/3,421) of which had normal or unknown G6PD status. In the 1,975 patients treated with chloroquine (CQ) alone, Hb fell to a nadir on day 2, before subsequently recovering rapidly and plateauing after day 7. Higher baseline Hb was associated with a greater absolute fall in Hb; in those with a baseline Hb ≤11.5 g/dL, 72.2% (182/252) had no fall in Hb during early follow-up. In the 1,446 patients treated with CQ+PQ, the Hb at day of nadir was only -0.13 g/dL (95%CI -0.27, 0.01; p=0.072) less than in patients treated with CQ alone. However, by day 42 the mean Hb was higher by 0.49 g/dL (95%CI 0.28 to 0.69; p<0.001) among patients treated with CQ+PQ compared to those treated with CQ alone. The Hb on day 42 was significantly lower (-0.72 g/dL, 95%CI -0.90, -0.54; p<0.001) in those patients with recurrent parasitaemia. In summary, the fall in Hb following the treatment of vivax malaria in patients enrolled in therapeutic clinical trials primarily relates to malaria, rather than treatment with PQ. Treatment with PQ leads to a higher overall Hb by day 42, likely due to prevention of recurrence.

1728

INTERMITTENT PREVENTIVE THERAPY WITH SULPHADOXINE-PYRIMETHAMINE VERSUS DIHYDROARTEMISININ-PIPERAQUINE FOR THE PREVENTION OF MALARIA AND IMPROVEMENT OF BIRTH OUTCOMES

Richard Kajubi[1], Teddy Ochieng[1], Abel Kakuru[1], Prasanna Jagannathan[2], Miriam Nakalembe[3], Theodore Ruel[4], Bishop Opira[1], Harriet Ochokoru[1], John Ategeka[1], Patience Nayebare[1], Tamara D. Clark[4], Diane V. Havlir[4], Moses R. Kamya[3], Grant Dorsey[4]

[1]Infectious Diseases Research Collaboration, Kampala, Uganda, [2]Stanford University, Stanford, CA, United States, [3]Makerere University College of Health Sciences, Kampala, Uganda, [4]University of California San Francisco, San Francisco, CA, United States

In recent studies, intermittent preventive treatment of malaria in pregnancy (IPTp) with dihydroartemisinin-piperaquine (DP) was superior to sulfadoxine-pyrimethamine (SP) at reducing the risk of maternal malaria and placental malaria. However, previous studies were not sufficiently powered to look at differences in birth outcomes and SP was dosed less frequently than the updated recommendations of once a month. To address some of these limitations we conducted a double-blinded, randomized, controlled trial of 782 HIV-uninfected pregnant women in Busia District in eastern Uganda, an area where malaria is highly endemic and SP resistance is widespread. Participants between 12 and 20 weeks gestation were randomized in equal proportions to IPTp with monthly SP or monthly DP. The primary outcome was the risk of a composite adverse birth outcome defined as low birth weight (LBW), preterm birth, or small for gestation age among live births. Secondary outcomes included measures of malaria during pregnancy and at delivery, individual adverse birth outcomes, and measures of safety. Among enrolled women, 687 (87.9%) were followed through delivery. There was no significant difference in the risk of our composite adverse birth outcome between the DP and SP treatment arms (16.0% vs 18.2%, p=0.45). However, among primagravid women, there was a trend towards a lower risk of LBW in the DP arm compared to the SP arm (5.5% vs 14.3%, p=0.08). During pregnancy, DP was associated with a significantly lower incidence of symptomatic malaria (0.02 vs 0.52 episodes PPY, p<0.001), parasite prevalence (0.5% vs 30.8%, p<0.001), and anemia (9.9% vs 19.7%, p<0.001). At delivery, DP was associated with a lower risk of placental malaria by placental blood smear (0.3% vs 8.8%, p=0.001), placental blood LAMP (2.1% vs. 22.4%, p<0.001), and histopathology (28.4% vs 61.2%, p<0.001). Both regimens were safe and well tolerated. In our setting monthly IPTp with DP was safe and far superior to SP in the prevention of maternal malaria, maternal anemia, and placental malaria, however, this did not translate into a clear benefit for reducing the risk of adverse birth outcomes.

1729

A RANDOMIZED CONTROLLED TRIAL OF REGULARLY DOSED PARACETAMOL (ACETAMINOPHEN) TO REDUCE RENAL DYSFUNCTION IN *PLASMODIUM KNOWLESI* MALARIA VIA REDUCTION OF CELL FREE HEMOGLOBIN MEDIATED OXIDATIVE DAMAGE; PACKNOW

Daniel J. Cooper[1], Matthew J. Grigg[1], Katherine Plewes[2], Giri S. Rajahram[3], Kim A. Piera[1], Timothy William[4], Federica Barzi[1], Jayaram Menon[3], Glenn Koleth[3], Aatish Patel[5], Tsin W. Yeo[6], Arjen M. Dondorp[2], Nicholas M. Anstey[1], Bridget E. Barber[1]

[1]Menzies School of Health Research, Darwin, Australia, [2]Mahidol Oxford Tropical Medicine Research Unit, Faculty of Tropical Medicine, Mahidol University, Bangkok, Thailand, [3]Sabah Department of Health, Kota Kinabalu, Sabah, Malaysia, [4]Jesselton Medical Centre, Kota Kinabalu, Sabah, Malaysia, [5]Infectious Diseases Society Sabah-Menzies School of Health Research Clinical Research Unit, Kota Kinabalu, Sabah, Malaysia, [6]Lee Kong Chian School of Medicine, Nanyang Technological University, Singapore, Singapore

Plasmodium knowlesi is the most common cause of human malaria in Malaysia and is present throughout SE Asia. Haemolysis associated acute kidney injury (AKI) is a frequent complication. Short and long term adverse consequences of AKI are well characterised; adjunctive therapies are therefore needed to reduce the impact of AKI in malaria. In falciparum malaria, cell free haemoglobin (CFHb) mediated oxidative damage and endothelial activation contribute to AKI. Paracetamol improves renal function in falciparum malaria, likely via inhibiting CFHb induced oxidative damage. The aim of PACKNOW is to assess whether regularly dosed paracetamol reduces the incidence and severity of AKI in knowlesi malaria by attenuating haemolysis mediated mechanisms. PACKNOW is a two arm, open label randomised controlled trial of adjunctive paracetamol versus no paracetamol in patients aged ≥5 years with knowlesi malaria, conducted over 18 months at 4 hospitals in Sabah, Malaysia. Enrolments finished in 2018, with 379 Pk patients randomised: 188 to regular paracetamol, and 191 to no paracetamol. Median age was 36 years, 85% were male. Thirty five patients (8.8%) had severe malaria on enrolment. AKI by KDIGO criteria was present on enrolment in 115 (30%) patients (60 in the control arm, 55 in the paracetamol arm); and 24 (6%) patients developed AKI after enrolment. The primary endpoint is change in creatinine from enrolment to 72 hours using enrolment creatinine as a covariate (by ANCOVA), stratified by CFHb. Secondary endpoints include longitudinal changes in markers of oxidative stress (plasma F_2-isoprostanes and isofurans), endothelial activation, and biomarkers of AKI over 72 hours. Laboratory analyses are underway; results from the PACKNOW study will be presented. Paracetamol is safe and widely available; if a renoprotective effect is demonstrated, this trial will support administration

of regularly dosed paracetamol to patients with knowlesi or falciparum malaria - species associated with significant haemolysis and AKI. Secondary outcomes will determine mechanisms of haemolysis induced AKI in malaria, and other haemolytic diseases.

1730

HEPATIC SAFETY OF REPETITIVE TREATMENT WITH PYRONARIDINE-ARTESUNATE (PA) AND ARTEMETHER-LUMEFANTRINE (AL) IN PATIENTS WITH UNCOMPLICATED MALARIA IN BOBO-DIOULASSO, BURKINA FASO

Yves D. Compaore

Institut de Recherche en Sciences de la Sante (IRSS), Bobo-Dioulasso, Burkina Faso

Although its high effectiveness against malaria, PA has been associated with sparse cases of increased AST/ALT suggesting high risk of hepatotoxicity if used for retreatment in patients. In this study, we aimed to evaluate the real hepatic impact of the retreatment with PA versus AL in patients with uncomplicated malaria in Burkina Faso. From August, 2012 to November, 2015 patients with uncomplicated malaria were randomized into PA and AL arms and followed up during 2 years. Each subsequent episode was treated with the same ACT. Hepatotoxicity was assessed using spectrophotometric assay for AST/ALT, PAL, total and direct bilirubin measurement on days 0 (baseline), 3, 7, 28 and unexpected days during a 42-day follow-up. The risk of hepatic adverse events (HAE) was compared between 2 groups in each arm: first administration of study drug and retreatment groups. The associations between treatment modalities and the risks of HAE were determined. In PA arm, the overall risk of serious HAE (severity grade ≥ 3) was reduced in the re-treated group (1.99%) compared to the first administration group (6.82%), p = 0.005. In AL arm, this risk was similar between the re-treated and the first administration groups with 3% versus 3.38% respectively, p = 0.769. One adverse event complying with a Hy's law case was registered in the first administration group of PA arm. After adjusting for age, sex and hepatic biochemical parameters, the odds of adverse events attributable to increased concentrations of ALT were reduced by 70% (p=0.004) and 66% (p=0.018) in retreated patients from PA and AL arms respectively, compared to the groups of first drugs administration. Retreated patients from AL arm presented 80% less risk of increased ASAT like AE. Retreatment with PA had shown a better overall hepatic safety profile than that of its first administration. Retreatment with PA was as well tolerated by the liver as retreatment with AL.PA could be a good alternative for the treatment of repeated malaria episodes in endemic areas.

1731

EFFICACY AND SAFETY OF PYRONARIDINE-ARTESUNATE AND ARTEMETHER-LUMEFANTRINE TREATMENT OF UNCOMPLICATED *PLASMODIUM FALCIPARUM* MALARIA AND MOLECULAR DETECTION OF RESIDUAL PARASITEMIA IN KENYAN CHILDREN

Petra Mens[1], Johanna Roth[1], Patrick Sawa[2], Nic Makadio[2], George Omweri[2], Victor Osoti[2], Selpha Okach[2], Felix Choy[1], Henk Schallig[1]

[1]Academic Medical Centre, Amsterdam, Netherlands, [2]International Centre of Insect Physiology and Ecology, Mbita, Kenya

Artemisinin-resistance is rapidly rising in South-East Asia and may spread to Africa. Therefore, alternative treatment options must become available. Pyronaridine-artesunate (PA) is a new artemisinin-based combination therapy. Efficacy and safety of PA was compared with artemether-lumefantrine (AL) to treat uncomplicated *Plamodium falciparum* malaria in children. Furthermore, monitoring parasite clearance dynamics after treatment is needed to determine whether responsiveness to artemisinin-based combination therapies (ACT) is changing in Africa. A phase III open-label randomized controlled non-inferiority trial was conducted in Western Kenya. Children aged 6 to 144 months and microscopically confirmed *P. falciparum* malaria were randomly assigned in a 1:1 ratio to receive PA or AL, dosed according to bodyweight, for three days and safety and efficacy of these combinations was assessed. In addition, parasite clearance was evaluated over 7 days following start of treatment by qPCR and direct-on-blood PCR Nucleic Acid Lateral Flow Immunoassay (db-PCR-NALFIA), a simplified molecular malaria diagnostic. ay-28 adequate clinical and parasitological response in the per-protocol population, PCR-corrected for reinfections, was 98.9% for PA and 96.4% for AL. Adverse events occurred in 41.6% and 34.4% of patients in the PA group and the AL group, respectively. Residual parasitemia (dayD 7) was detected by qPCR in 37.1% of AL-treated children and in 46.1% of PA-treated participants. Db-PCR-NALFIA detected residual parasites at day 7 in 33.3% and 30.3% of AL and PA-treated participants, respectively. qPCR determined parasitemia at day 7 was associated with increased prevalence and density of gametocytes at baseline and during follow-up. A positive db-PCR-NALFIA outcome at day 7 was associated with treatment failure, but this association was not found for qPCR. PA was well tolerated, efficacious and non-inferior to AL for the treatment of uncomplicated *falciparum* malaria in children and inclusion of PA in pediatric malaria treatment programs should be considered. To predict treatment outcome, db-PCR-NALFIA may be more suitable than qPCR.

1732

DRUG RESISTANCE ASSESSMENT OF *PLASMODIUM FALCIPARUM* AND *P. VIVAX* MALARIA IN NINH THUAN PROVINCE, SOUTH-CENTRAL VIETNAM

Nguyen C. Phong[1], Marina Chavchich[2], Huynh H. Quang[3], Nguyen N. San[1], Nguyen V. Thanh[1], Geoffrey W. Birrell[2], Ilin Chuang[4], Nicolas J. Martin[5], Nguyen D. Manh[1], **Michael D. Edstein**[2]

[1]Vietnam People's Army Military Institute of Preventive Medicine (MIPM), Hanoi, Vietnam, [2]Australian Army Malaria Institute (AAMI), Brisbane, Australia, [3]Institute of Malariology, Parasitology and Entomology (IMPE), Quy Nhon, Vietnam, [4]US Navy Medical Research Center (NMRC), Silver Spring, MD, United States, [5]US Naval Medical Research Center-Asia (NMRC-A), Singapore, Singapore

Plasmodium falciparum and *Plasmodium vivax* malaria resistance to the first-line treatment regimens of dihydroartemisinin-piperaquine (DHA-PPQ) and chloroquine (CQ), respectively, has been reported in southern Vietnam. Information on the distribution of DHA-PPQ and CQ resistance in different regions of the country is required to inform on antimalarial drug policy for the Vietnam Ministry of Health. Such information will also be needed for implementing malaria elimination strategies. To assist in identifying and monitoring for drug resistance MIPM, with support from IMPE, AAMI and NMRC-A conducted therapeutic efficacy trials in Phuoc Chien Commune (Ninh Thuan Province) in south-central Vietnam. In 2015-2016, 27 patients with *P. falciparum* mono-infections consented to be treated and after randomization received either 4 days of artesunate followed by 3 days of DHA-PPQ (n=13) or 3 days of artemether-lumefantrine (AM-LUM) (n=14). Sixteen patients received 3 days of CQ for *P. vivax* mono-infection treatment. In 2015 and 2016, malaria cases markedly decreased throughout Vietnam, which was also seen at Phuoc Chien Commune resulting in a low number of participants for the two studies. Nevertheless, the clinical and efficacy parameter data obtained after treatment, as well as molecular analysis of genetic markers of drug resistance and *in vitro* drug susceptibility of clinical *P. falciparum* isolates did not reveal reduced susceptibility to artesunate, DHA-PPQ or AM-LUM resistance. All falciparum patients were blood film negative by day 3 after starting treatment and no recrudescences were observed during a 42 day follow-up period. CQ-resistant *P. vivax* malaria did not appear to be present in the small number of patients evaluated (n=16) with two patients having a recurrence of vivax malaria on day 28 of follow-up, but with low drug concentrations. Treatment regimens were well tolerated and no serious adverse events were reported in both studies. Demographic,

clinical, molecular and *in vitro* data, as well as blood drug exposure concentrations will be presented and the application of the information for malaria elimination will be discussed.

1733

THE EFFECT OF DIFFERENT DOSING REGIMENS ON THE ANTIMALARIAL EFFICACY OF ARTESUNATE-MEFLOQUINE: A POOLED ANALYSIS OF INDIVIDUAL PATIENT DATA

Elizabeth Ashley[1], WWARN ASMQ Dose Impact Study Group[2]

[1]Mahidol Oxford Tropical Health Network, Yangon, Myanmar, [2]WorldWide Antimalarial Resistance Network, Oxford, United Kingdom

Artesunate-mefloquine (AS-MQ) is one of the leading artemisinin combination therapies (ACTs) used to treat uncomplicated falciparum malaria worldwide. Different dosing regimens have been used since it was first introduced, culminating in the creation of a fixed-dose combination which was prequalified by the World Health Organization in 2014. AS-MQ has been used extensively in Asia but there is only limited experience of its use in sub-Saharan Africa where malaria is predominantly a disease of under five year olds. Pooling individual patient data is a powerful tool for exploring the impact of mg/kg dosing on efficacy of antimalarial medicines in different patient groups, particularly young children who are often underrepresented in clinical drug development. In this analysis of data from patients treated with different regimens of AS-MQ we explore the relationship between mg/kg dose of mefloquine and timing of dosing and parasite recrudescence. A systematic search of the literature (PubMed, Embase, Web of Science) was conducted to identify all studies published between 1990 and 2017, in which patients were enrolled and treated with AS-MQ. Investigators were invited to share their data and participate to the study group. Individual patient data were pooled using a standardised methodology. Univariable and multivariable risk factors for parasite recrudescence were identified using a Cox's regression model with shared frailty across the study sites. The primary endpoint was the PCR-adjusted risk of *Plasmodium falciparum* recrudescence by day 42. Data from 37 studies from 19 countries from Asia, Africa and South America were shared, including 9445 patients with 211 recrudescent and 472 new infections reported. The majority of patients were adults (50), 15% were children younger than 5 years of age and 35% were children 5-15 year olds. Results of the analysis will be presented and discussed, focusing on the effect of dose on the risk of recrudescence.

1734

IMPACT OF CYP2D6 ON PRIMAQUINE AND TAFENOQUINE EFFICACY IN *PLASMODIUM VIVAX* MALARIA PHASE 3 CLINICAL TRIALS

Pamela St. Jean[1], Gavin Koh[2], Khadeeja Mohamed[2], Stephan Duparc[3], Justin Green[2]

[1]PAREXEL International Corp, Waltham, MA, United States, [2]GlaxoSmithKline, Uxbridge, United Kingdom, [3]Medicines for Malaria Venture, Geneva, Switzerland

There is emerging evidence that metabolic activation of primaquine (PQ) by CYP2D6 is required for anti-hypnozoite activity. As tafenoquine (TQ) is in the same class as PQ, we examined the impact of CYP2D6 metabolism on PQ and TQ efficacy in two previously reported phase 3 clinical studies, DETECTIVE (NCT01376167) and GATHER (NCT02216123). Both arms were in combination with chloroquine. We derived CYP2D6 metabolizer class by summing the activity of a subject's two CYP2D6 *alleles with a value of 0 for a null allele, 0.5 for a reduced activity allele and 1 for a full function allele. Subjects with activity sums of 0, 0.5 to 1, and 1.5 to 2 were classified as poor (PM), intermediate (IM) and extensive (EM) metabolizers, respectively. Subjects who were confirmed recurrence-free or had a recurrence over 6 months post treatment were included in the analyses. Logistic regression models with geographic region as a covariate were fitted to assess the effect of CYP2D6 metabolizer class on recurrence-free efficacy by treatment arm and study. As there were ≤3 PM per arm by study, the PMs and IMs were combined and compared to the EMs. Allele frequencies varied by geographic region aligning with published regional frequencies. In the DETECTIVE PQ arm, recurrence risk increased with reduced activity (N=116, Odds Ratio (OR) = 2.36, p=0.032) where all 3 PM had recurrence. When PM were excluded from analysis, the effect in the DETECTIVE PQ arm was not significant (p=0.10). No evidence of an effect was seen in the DETECTIVE TQ arm (N=231, OR=1.05, p=0.44) in which 1 of 3 PM had recurrence. No effect was seen in the GATHER study for either arm (TQ arm N=134, OR=0.89, p=0.60; PQ arm N=65, OR=0.76, p=0.64). The 1 PM in GATHER was in the TQ arm and recurrence-free. In summary, neither study showed evidence of a CYP2D6 effect on TQ efficacy. These results suggest that PMs are more likely to suffer a recurrence with PQ treatment (3 of 3 PMs with a recurrence), but not with TQ treatment (1 of 4 PMs with a recurrence); however, a limitation of these findings is the small number of PM subjects and that we cannot distinguish relapses from new infections in this study.

1735

SAFETY, EFFICACY, TOLERABILITY AND PHARMACOKINETICS OF AZITHROMYCIN PLUS PIPERAQUINE AS A CANDIDATE FOR INTERMITTENT PREVENTIVE TREATMENT FOR MALARIA IN PREGNANCY

Brioni R. Moore[1], John Benjamin[2], Sam Salman[3], Madhu Page-Sharp[1], Moses Laman[2], Kevin T. Batty[1], Ivo Mueller[4], Stephen Rogerson[5], Timothy M. Davis[3]

[1]School of Pharmacy and Biomedical Sciences, Curtin University, Perth, Australia, [2]Vector Borne Disease Unit, Papua New Guinea Institute of Medical Research, Madang, Papua New Guinea, [3]UWA Medical School, University of Western Australia, Perth, Australia, [4]Walter and Eliza Hall Institute of Medical Research, Parkville, Australia, [5]Doherty Institute, Melbourne, Australia

Malaria in pregnancy remains a major cause of maternal anaemia, low birthweight and increased perinatal mortality. One of the strategies used to improve obstetric outcome is intermittent preventive treatment of malaria in pregnancy (IPTp). The World Health Organization-recommended IPTp is sulfadoxine-pyrimethamine (SP) but the spread of SP-resistant *Plasmodium falciparum*, and relatively short half-lives of the component drugs has prompted investigation into alternative therapies. Azithromycin (AZI) is one antimalarial compound that has received recent consideration given its known safety during pregnancy and efficacy against other pathogens, including sexually transmitted infections. The present study investigated the combination of AZI plus PQ as a candidate for future IPTp. One hundred and fifty pregnant Papua New Guinean women (>14 weeks gestation) were recruited and randomised to receive either AZI+PQ (1 g AZI plus 960 mg PQ phosphate) daily for three days, or a single dose of SP (1,500 mg SDOX and 75 mg PYR; current PNG IPTp regimen). Detailed follow-up assessment was performed on Days 1, 2, 3, 4, 7, 14, 21, 28, 42 and time of delivery for efficacy, safety and tolerability outcomes. Each participant recruited into the intensive pharmacokinetic (PK) sampling protocol (first 30 women in AZI+PQ treatment group) were randomly assigned to 7 of 18 time points (1, 2, 3, 6, 12, 24, 32, 40, 48 and 72 h, and Days 4, 5, 7, 10, 14, 21, 28 and 42) over the 42 day study period. Breast milk samples (fore- and hind-milk) for drug assay were collected from all participants for 28 days after the establishment of lactation. This study reports the first investigation of AZI+PQ as candidate IPTp or for pregnant women. Preliminary data demonstrate a good safety, efficacy and tolerability profile for AZI+PQP. PK analysis of all drug assay samples will be performed using liquid chromatography mass spectrometry with population PK modelling of plasma concentration-time data. The results of this study could have profound impacts on future IPTp regimens and women's health in malaria endemic regions.

1736

HEMOGLOBIN DECLINE IN G6PD NORMAL *PLASMODIUM VIVAX* PATIENTS TREATED WITH CHLOROQUINE AND TAFENOQUINE OR PRIMAQUINE IN THE PHASE 3 TAF112582 (DETECTIVE) STUDY

Khadeeja Mohamed[1], Thomas Drury[1], Gavin C. Koh[1], Stephan Duparc[2], Justin A. Green[1]

[1]GSK, Uxbridge, United Kingdom, [2]Medicines for Malaria Venture, Geneva, Switzerland

Tafenoquine (TQ) is a novel 8-aminoquinoline in development for radical cure of *Plasmodium vivax* malaria but like all 8-aminoquinolines can cause haemoglobin decline in G6PD deficient individuals. TAF112582 (DETECTIVE Part 2, NCT01376167) was a phase 3 randomised, double-blind, placebo-controlled study. This multi-centre study recruited 522 G6PD normal patients with *P. vivax* malaria. Patients in all three treatment arms received chloroquine and were randomised to receive TQ 300mg single-dose (N=260), placebo (N=133) or primaquine (PQ) 15mg daily for 14 days (N=129). We report a *post-hoc* regression analysis of haemoglobin decline in the study to investigate a possible excess of haemoglobin declines from baseline observed in TQ group (5% TQ vs 1% placebo and 2% PQ patients with >3g/dL decline). The outcome of interest was maximum haemoglobin decline from baseline over the first 15 days post treatment. The covariates used in the final model were baseline haemoglobin, G6PD enzyme activity and baseline *P. vivax* parasite count. Other explanatory variables explored were geographical region, gender, age and baseline urea. Results: There was an overall decline in haemoglobin in all treatment groups. The maximum decline in haemoglobin was 1.22 g/dL (95% CI 1.13 - 1.30 g/dL) in the TQ arm, 1.02 g/dL (95% CI 0.90, 1.14 g/dL) in the placebo arm, and 1.11 g/dL (95% CI 0.98 - 1.23 g/dL) in the PQ arm. Haemoglobin declines in G6PD normal patients in the study were partly due to higher baseline haemoglobin and parasite count and lower G6PD enzyme activity. After adjusting for baseline haemoglobin, parasite count and G6PD enzyme activity, although there was a larger decline in haemoglobin in patients treated with TQ compared to placebo this treatment difference was only 0.19 g/dL [95% CI 0.04 - 0.34 g/dL], and thus not considered clinically significant.

1737

DEALING WITH INDETERMINATE OUTCOMES IN ANTIMALARIAL EFFICACY TRIALS: A COMPARISON BETWEEN COMPLETE CASE ANALYSIS, MULTIPLE IMPUTATION AND INVERSE PROBABILITY WEIGHTING

Prabin Dahal[1], Kasia Stepniewska[1], Philippe J. Guerin[1], Umberto D'Alessandro[2], Ric N. Price[1], Julie A. Simpson[3]

[1]WorldWide Antimalarial Resistance Network, Centre for Tropical Medicine and Global Health, Nuffield Department of Clinical Medicine, University of Oxford, Oxford, United Kingdom, [2]Medical Research Council Unit, Fajara, Gambia, [3]Centre for Epidemiology and Biostatistics, Melbourne School of Population and Global Health, The University of Melbourne, Melbourne, Australia

Antimalarial clinical efficacy studies for uncomplicated *Plasmodium falciparum* malaria frequently encounter situations in which parasite molecular typing is unable to discriminate between parasitic recurrence, either new infection or recrudescence. The current WHO guideline recommends excluding these individuals with indeterminate outcomes in a complete case (CC) analysis. Data from the four artemisinin-based combination trial was used to compare the performance of multiple imputation (MI) and inverse probability weighting (IPW) with the standard CC analysis for dealing with indeterminate recurrences. A total of 3,369 study participants with molecularly defined parasitic recurrence treated with three artemisinin-based combination therapies were used to represent a complete dataset. A set proportion of recurrent infections (10, 30 and 45%) were reclassified as to missing using two different mechanisms: a completely random selection (mechanism 1); missingness dependent on treatment and transmission intensity (mechanism 2). The performance of MI, IPW and CC approaches in estimating the Kaplan-Meier (K-M) probability of drug efficacy was then compared. Performance measures (bias, relative bias, standard error and coverage) were reported as an average from 1,000 simulation runs. The CC analyses resulted in absolute overestimation of drug efficacy by up to 1.7% and were associated with reduced precision and poor coverage across all the missingness scenarios studied. Both MI and IPW method performed better (unbiased and greater efficiency) compared to CC analysis. The widely used CC approach overestimates antimalarial efficacy. The IPW and MI procedures provided efficient and unbiased estimation of antimalarial efficacy and should be considered when reporting the results of antimalarial clinical trials, especially in the areas of high transmission where the proportion of indeterminate outcomes could be large.

THE PHARMACOKINETICS OF PRIMAQUINE AND ITS METABOLITES IN HEALTHY CAMBODIAN ADULTS WITH VARIOUS CYP2D6 GENOTYPES

Michele Spring[1], Pattaraporn Vanachayangkul[1], Chanthap Lon[2], Darapiseth Sea[2], Somethy Sok[2], Soklyda Chann[2], Sokhei Hom[2], Mali Ittiverakul[1], Chanikarn Kodchakorn[1], Montri Arsanok[1], Kheangheng Thay[2], Worachet Kuntawunginn[1], David Saunders[3], Huy Rekol[4], Mariusz Wojnarski[1], Philip Smith[1]

[1]Armed Forces Research Institute of Medical Sciences, Bangkok, Thailand, [2]Armed Forces Research Institute of Medical Sciences, Phnom Penh, Cambodia, [3]US Army Medical Material Development Activity, Fort Detrick, MD, United States, [4]Cambodia National Malaria Program (CNM), Phnom Penh, Cambodia

The Cambodian government declared elimination of *Plasmodium vivax* in 2025, which will require increased administration of primaquine for *P. vivax* radical cure. Recent research suggests the hepatic CYP450 2D6 enzyme to be responsible for metabolism of primaquine to the active metabolites required for hypnozoite clearance. The effects of different 2D6 genotypes on the pharmacokinetics of primaquine in populations living in vivax endemic areas are not well characterized. We previously reported on the various CYP2D6 genotypes prevalent in a subset of 40 Cambodians and found 55% allelic frequency of the reduced activity 2D6*10 allele, most often paired with a normal activity allele or another reduced allele. In 2017, we re-consented 27 of the 40 volunteers to participate in a primaquine pharmacokinetic study. Using the CYP2D6 AS-A scoring system, 1 volunteer was found to have a score of 2, 13 volunteers had a score of 1.5, 12 had a score of 1.0 and 1 Undetermined (UNDET) with a genotype of *5/*10 DUP, which could lead to scoring as either 0.5 or 1.0. Thus, all of the volunteers were predicted to be Extensive Metabolizers (EMs), except the UNDET volunteer, who could be predicted to be either an EM or Intermediate Metabolizer (IM) phenotype. Primaquine (PQ) and its metabolite levels were measured in blood and urine by UPLC-MSMS over the subsequent 24 hours after oral administration of single dose primaquine (15 mg) in order to correlate CYP2D6 genotype with metabolite concentrations and phenotype. Initial results show the plasma PQ C_{max} values were 65.2 61.6, and 101.2ng/ml for AS-A scores of ≥1.5, 1.0, and UNDET, respectively, which suggested the AS-A scores of 1.5 and 1.0 metabolized similarly and the UNDET had an IM phenotype. T_{max} results were similar for all 3 AS-A scores and to results seen previously (range 2-3.1 hours). Carboxyprimaquine, the major metabolite generated through the monoamine oxidase pathway, showed similar C_{max} values for all (452.0, 460.8 and 451.7ng/ml) and T_{max} of 7.7, 8.8 and 6 hours AS-A scores of ≥1.5, 1.0, and UNDET, respectively. Full pharmacokinetic analysis of primaquine metabolites in both blood and urine will be presented.

TAFENOQUINE FOR MALARIA PREVENTION

Geoffrey S. Dow

60 Degrees Pharmaceuticals LLC, Washington, DC, United States

The development of tafenoquine for malaria prevention was completed by 60° Pharmaceuticals (60P) in collaboration with the U.S. Army in late 2017. Tafenoquine is currently undergoing priority review by the U.S. Food and Drug Administration for malaria prevention for up to six months in adults. Assuming regulatory approval is obtained, commercial launch is targeted for early 2019. Unlike the more well-known *Plasmodium vivax* indication where tafenoquine is given as a single dose to symptomatic individuals, the proposed label submitted by 60P to regulators involves continuous weekly dosing for up to six months in adults at risk of contracting malaria. Data from peer-reviewed clinical trials suggest that tafenoquine has activity against both *P. falciparum* and *P. vivax*. Structural, non-clinical, and clinical data from the literature suggest tafenoquine does not have a neurologic liability, but that G6PD testing is required to prevent inadvertent use in individuals with severe deficiency. Therefore, should tafenoquine receive marketing authorization, it may represent an improvement over the standard of care (mefloquine, chloroquine, daily drugs) in jurisdictions with robust G6PD screening capability. One can envisage, following the generation of additional clinical data, expansion of the proposed label to include children, dosing for up to 12 months, prevention of malaria amongst travelers between malaria-endemic countries, and outbreak prevention in countries declared malaria-free by the World Health Organization. 60P plans to conduct several post-marketing studies to allow these additional potential uses of tafenoquine for malaria prevention and eradication to be realized. The opinions expressed herein are the author's own and do not necessarily reflect those of the United States Army or Department of Defense.

ASYMPTOMATIC MALARIA IN HOUSEHOLD MEMBERS OF FEBRILE CHILDREN ATTENDING CLINIC IN COASTAL TANZANIA

Zackary Park[1], Edward Lwidiko[2], Madelyn Connor[1], Ozkan Aydemir[3], Patrick Marsh[3], Jeffrey Bailey[3], Jonathan J. Juliano[1], Billy Ngasala[2], Jessica T. Lin[1]

[1]Division of Infectious Diseases, University of North Carolina School of Medicine, Chapel Hill, NC, United States, [2]Department of Parasitology and Medical Entomology, Muhimbili University of Health and Allied Sciences, Dar es Salaam, United Republic of Tanzania, [3]Department of Medicine and Program in Integrative Bioinformatics, University of Massachusetts Medical School, Worcester, MA, United States

Since asymptomatic malaria infections greatly outnumber symptomatic cases in low-endemic settings, submicroscopic parasitemias may be an important invisible reservoir in areas seeking malaria elimination. However, the relationship of asymptomatic to symptomatic cases is not well-established, with recent genetic studies suggesting that parasites that circulate asymptomatically may differ from those causing symptomatic infections. We used a clinic-based reactive case detection scheme to identify persons with asymptomatic parasitemia in coastal Tanzania, with the goal of examining the genetic relatedness of parasites causing asymptomatic vs. symptomatic infection. Asymptomatic persons accompanying febrile children presenting for care at the Yombo Clinic in Bagamoyo, Tanzania from March to April 2017 were screened for parasitemia by rapid diagnostic test (RDT) and peripheral blood smear, with DNA extracted from dried blood spots used for species-specific real-time PCR (qPCR) targeting the 18S ribosomal gene. Among 164 study participants who denied fevers/chills in the 3 days prior to enrollment, 71% were mothers, 21% were fathers, and 8% were other family members bringing their child to care. The median age was 32.5 (range 13-57), and 16% reported a history of malaria within the past year, while 75% reported malaria in their lifetime. We found no correlation between these factors and a positive malaria screening result. Malaria prevalence in the asymptomatic contacts was 3.1% (5/160) by RDT and 13.1% (21/160) by qPCR. Age, gender, parasite density, housing materials and bed net use in the febrile children were also not associated with positive malaria status in their asymptomatic contacts. We are employing hybrid capture-based target enrichment and multi-locus deep sequencing to investigate the genetic relatedness of parasites within and between households, and whether parasites causing symptomatic versus asymptomatic infections cluster separately.

Chan School of Public Health, Boston, MA, United States

Countries in the Asia-Pacific have committed to eliminating malaria by 2030. Ownership of cellphones and spatial coverage by cellphone service providers are rapidly expanding across the region. Cellphones are increasingly being used for a wide variety of public health purposes and research on malaria including sms and smartphone-based case reporting, tracking interventions and public health messaging, as well as newer techniques such as using call detail records to quantify the impact of population movement on malaria distribution and development of smartphone-based automated diagnosis. Many cellphone-based reporting systems for malaria require ongoing connection to the internet to upload data whilst some permit offline data storage for later uploading once sufficient signal strength is available. The utility of these techniques depends heavily on whether people with malaria have access to cellphones and on the coverage of cellphone services in malaria endemic areas. This study aimed to determine the patterns of cellphone usage among people with malaria and map cellphone signal strength in relation to malaria burden in Southeast and South Asia. Over 5000 people with confirmed malaria infection in Bangladesh, Cambodia, northeast India, Lao PDR, Myanmar, Thailand and Vietnam were surveyed about their usage of cellphones including whether they have a phone, if they share it and which service provider they use. In addition, publicly available data on over 2 million cell tower locations were analysed to determine the spatial distribution of cellphone service provision by different providers in relation to malaria burden in these countries. From this analysis, locations were identified where cellphones currently have the greatest potential to help accelerate malaria elimination in these countries and locations where improvement of cellphone service coverage would be of most benefit. THE IMPACT OF MATERNAL MALARIA INFECTION DURING PREGNANCY ON INFANT MALARIA RISK: A COHORT STUDY IN WESTERN KENYA

Jonathan S. Schultz[1], Mi Tran[1], Ibrahim Daud[2], Sidney Ogolla[2], Arlene Dent[3], Rosemary Rochford[1]

[1]University of Colorado, Aurora, CO, United States, [2]KEMRI, Kisumu, Kenya, [3]Case Western Reserve University, Cleveland, OH, United States

More than 125 million pregnant women are at risk for malaria annually. In Sub-Saharan Africa it is estimated that 1 in 4 women have placental malaria at the time of delivery. Placental malaria is associated with adverse maternal, fetal, and infant health outcomes. In Kenya, the Ministry of Health adopted Intermittent Preventive Treatment (IPT) for malaria and provision of insecticide-treated nets as a national strategy for malaria prevention in pregnancy, which has reduced the incidence of placental malaria. However, little is known about the effects of maternal asymptomatic parasitemia on infant outcomes. The objective of this study is to examine the impact of maternal untreated malaria parasitemia during pregnancy, detected retrospectively by qPCR, on infant illnesses, including malaria, through a longitudinal prospective cohort study conducted at Chulaimbo Hospital in the Kisumu District of Kenya, from June 2011 to July 2015. Demographic, medical, socioeconomic data and sera for peripheral and placental malaria were obtained. Infants were followed from birth to 24 months with scheduled follow-up appointments at 6, 10, 14, and 18 weeks, then every three months until 24 months of age. Diagnoses from scheduled follow-ups and sick visits were recorded. A total of 149 infants and mothers were included, of which 93 (62%) had a positive PCR for malaria during pregnancy. Maternal characteristics for both malaria infected mothers and non-malaria infected mothers were similar. Sixty (40%) infants were diagnosed with malaria during the follow up period. There were no significant differences observed between children diagnosed with malaria. Multivariate analyses showed no significant association between maternal asymptomatic parasitemia in pregnancy with infant diagnoses of malaria in the 2-year follow up period after adjusting for confounding variables including age of the mother, infant age, sex, birth weight and maternal education using multivariable logistic regression. Our data suggest that newborns may not be effected by maternal asymptomatic parasitemia during pregnancy and they are not at increased risk of malaria.

PLASMODIUM FALCIPARUM MULTIPLICITY OF INFECTION IN MALAWI

Dominique E. Earland[1], Andrea G. Buchwald[1], Alick Sixpence[2], Mabvuto Chimenya[2], Milius Damson[2], Karl Seydel[3], Don P. Mathanga[2], Terrie E. Taylor[3], Miriam K. Laufer[1]

[1]Division of Malaria Research, Institute for Global Health, University of Maryland School of Medicine, Baltimore, MD, United States, [2]Malaria Alert Center, University of Malawi College of Medicine, Blantyre, Malawi, [3]College of Osteopathic Medicine, Michigan State University, East Lansing, MI, United States

The likelihood of *Plasmodium falciparum* infection resulting in malaria illness is related to age, parasitemia, and parasite diversity. Multiplicity of infection (MOI), the number of unique parasite genotypes, may also contribute to the development of malaria disease. Previous studies in high transmission settings comparing symptomatic and asymptomatic infections have shown that high MOI infections are a risk factor for symptomatic illness, but MOI was not assessed after controlling for parasite density and age. Our aim was to examine the independent role of MOI on clinical disease. We hypothesized that increased MOI, after adjusting for parasite density, would be associated with symptomatic malaria. We conducted a two-year longitudinal cohort study of adults and children in a high transmission setting in Malawi; illness episodes were captured with active and passive surveillance. *P. falciparum* infection was detected using qPCR and all positive samples underwent genotyping using merozoite surface proteins (msp1, msp2) and glutamate-rich protein. Of 1,061 infections, 476 (44.9%) were symptomatic. Median MOI was 2 (IQR = 1, 3) and ranged from 1 to 10. Before adjusting for parasite density, higher MOI was associated with increased odds of clinical diseases (OR = 1.86, 95% CI: 1.36-2.55) and school-aged children had increased odds of symptomatic infection compared to children under five (OR = 2.25, 95% CI: 1.17-2.97). After controlling for repeated measures and parasite density, there was no association between MOI and presence of symptoms (OR = 1.23, 95% CI: 0.85-1.77). High parasitemia (>2,000 parasite/ul blood) was associated with an 80% increase in the odds of symptoms among children and a 60% increase in the odds of symptoms among adults. The strong association of parasite density and symptomatic illness may confound the effect of MOI or be due to improved sensitivity of genotyping when more parasites are present. In this high transmission setting, parasite density, but not MOI, was a strong predictor of clinical disease in the presence of *P. falciparum* infection.

1744

OPPORTUNITIES AND CHALLENGES TO STRENGTHEN DISEASE SURVEILLANCE TO SUPPORT MALARIA ELIMINATION IN THE PHILIPPINES

Mariska H. van der Zee[1], Inez A. Medado[2], Chris Drakeley[3], Fe Esperanza C. Espino[2], **Benjamin Palafox**[3]

[1]Access to Medicine Foundation, Amsterdam, Netherlands, [2]Research Institute for Tropical Medicine, Metro Manila, Philippines, [3]London School of Hygiene & Tropical Medicine, London, United Kingdom

The Philippines aims to eliminate malaria by 2030. To accelerate towards this goal, it is essential for the National Malaria Program to detect and treat all infections. However, current approaches limit the Program's the ability to respond effectively. The country is trialling novel diagnostic and transmission mapping techniques to improve surveillance for malaria elimination. This study evaluates the feasibility of integrating such techniques into the existing surveillance system. A case study approach was used, involving document review and semi-structured qualitative interviews of key informants purposefully selected from stakeholders working at all levels of the health system. Community- and provincial-level informants were selected from a project site in Occidental Mindoro. Interviews collected data on informants' beliefs on their organisation's readiness to integrate such novel techniques, and the various challenges and opportunities that they present, which were analysed thematically. A total of 32 interviews were conducted and 27 relevant documents reviewed. Most informants believed integration would require considerable financial resources for equipment and training, which local and national authorities may not prioritize or be able to afford. Other common barriers to integration included insufficient workforce, facilities' limited internet access, and the low quality and timeliness of data reporting from certain provinces. Some mentioned that strong advocacy in support of malaria elimination could help to create an environment receptive to innovation. Many of the barriers to integrating novel diagnostic techniques into the existing surveillance system are general health systems issues found in other pre-elimination countries. This suggests that adopting new measures for malaria control may not proceed if such systemic barriers are left unresolved. However where affordable, opting to invest in these new techniques could catalyse strengthening of the national surveillance system, and the health system more broadly. However, this will require advocacy to renew political support for elimination.

1745

FACTORS ASSOCIATED WITH MALARIA PARASITEMIA AND ANEMIA IN UGANDA: CROSS-SECTIONAL SURVEY OF 48 DISTRICTS

Catherine Maiteki[1], Samuel Gonahasa[1], Grant Dorsey[2], Jimmy Opigo[3], Adoke Yeka[1], Sheila Rugnao[2], Amy Lynd[4], Janet Hemingway[4], Martin Donnelly[4], Moses R. Kamya[1], Sarah G. Staedke[5]

[1]Infectious Diseases Research Collaboration, Kampala, Uganda, [2]University of California San Francisco, San Francisco, CA, United States, [3]Ministry of Health, Kampala, Uganda, [4]Liverpool School of Tropical Medicine, Liverpool, United Kingdom, [5]London School of Hygiene & Tropical Medicine, London, United Kingdom

A baseline cross-sectional community survey was conducted to assess the prevalence of malaria parasitemia and anemia in Uganda, for an ongoing trial of the impact of long-lasting insecticidal nets (LLINs) distributed in 2017-18. The survey included 104 clusters across 5 administrative regions. Households were randomly selected using two-staged cluster sampling; 50 households were enrolled per cluster. Eligible children aged 2-10 years had blood obtained for thick blood smear and to measure hemoglobin (aged 2-4 years). In March-June 2017, 5200 households were enrolled; 8852 children aged 2-10 years had blood smear results, and 3753 aged 2-4 years had hemoglobin results. Regional differences were seen in household wealth, house type, and adequate LLIN coverage (1 LLIN per 2 residents). Overall, parasite prevalence was 26.0% with wide geographic variation ranging from 8.0% in the southwest to 53.2% in eastcentral. In an adjusted analysis controlling for clustering within households, factors associated with parasitemia included increasing age (adjusted prevalence ratio (aPR) 1.07 per 1 year increase, 95% CI 1.06-1.08, p<0.001), living in a house with a wealth index in the lowest two tertiles (aPR 2.12, 95% CI 1.88-2.38, p<0.001), living in a house made from traditional materials (aPR 1.16, 95% CI 1.06-1.27, p=0.001), and living in a house without adequate LLIN coverage (aPR 1.31, 95% CI 1.15-1.49, p<0.001). Overall, the prevalence of anemia (hemoglobin < 10 g/dL) was 15.1% and also varied by region, ranging from 9.6% in the southwest to 20.2% in eastcentral. In an adjusted analysis, factors associated with anemia included region, decreasing age, living in a traditional house, and being parasitemic. Parasitemia was the strongest predictor of anemia (aPR 2.50, 95% CI: 2.12-2.95, p<0.001). These results indicate that the prevalence of parasitemia and anemia vary widely across Uganda, and that older children and those living in poorer households, made with traditional materials, and inadequate numbers of LLINs, are at highest risk of parasitemia; while the youngest children and those with parasitemia are at highest risk of anemia.

1746

CONTRIBUTION OF RAPID DIAGNOSIS TEST IN MALARIA CASE MANAGEMENT STRATEGY IN SENEGAL

Medoune Ndiop, Alioune Badara Gueye, Moustapha Cisse, Seynabou Gaye, Doudou Sene, Ibrahima Diallo

National Malaria Control Programm, Dakar, Senegal

According to WHO recommendations issued in 2004 for RDT use to improve quality and accuracy of the diagnosis, Senegal had introduced RDT (based on the detection of the antigen Histidin Rich Protein-2/HRP-2 specific for *Plasmodium falciparum*) in October, 2007. This diagnosis tool was supposed to: allow rational use of CTA, reduce the risk of CTA resistance development in the parasite, increase accuracy and reliability of morbidity data and avoid useless care-costs. Between 2001 and 2007, in the pre-RDT period, the proportion of all consultations due to malaria decreased from 39.7% in 2001 to 26.9% with confirmation cases rate by microscopy just around 10%.; after RDT introduction and change in definition from clinical to laboratory-confirmed, the proportion of all consultations due to malaria decreased from 9.1% in 2008 to 3.26% in 2017 and RDT realization who was around 15% at the beginning jumps to 99.55% in 2017. This was possible as RDT contributed to increase access to biological diagnostic to end users within the community by the mean of community health workers, due to easy use and rapidity in result delivery. In 2017, Senegal recorded 1,637,316 suspected cases (tested negative), all these cases should have been treated with a antimalarial if RDT was not conducted. Thus, by considering the cost of a CTA treatment at one US dollar, NMCP has realized almost 1,637,316 USD savings. RDT introduction into malaria case management was a realistic alternative to no functionality of the laboratories in the peripheral structures and to operational issues in the realization of the microscopic diagnosis Moreover, RDT was accepted by caregivers at any level as its allow rational use of time, credibility for the health system and increased confidence of the populations. RDT had largely contributed to the decrease of morbidity and mortality due to malaria, since it made possible detecting earlier and accurately malaria cases, treating it's with rapidity and by reducing the risks of transmission and evolution of cases to severe ones.

1747

THE BURDEN OF ANTIMALARIAL TREATMENT FAILURE IN AFRICA: EVIDENCE FROM HOUSEHOLD SURVEYS

Andria Mousa, Joseph Challenger, Azra Ghani, Lucy Okell

Imperial College London, London, United Kingdom

Despite recent scale-up of malaria control interventions such as provision of nets, access to artemisinin combination therapy (ACT) in Africa remains low. Antimalarial treatment failure can result in progression to severe disease or death and is due to several reasons including poor drug absorption, use of substandard or counterfeit drugs, non-adherence, or drug resistance. The latter is a particular problem when older drugs such as sulphadoxine-pyrimethamine (SP) are still used. Data on use of ACT, SP, chloroquine and quinine in 37,826 febrile children under five were obtained from Malaria Indicator Surveys (MIS) and Demographic and Health Surveys (DHS) from 22 African countries in which both rapid diagnostic tests (RDT) and microscopy had been performed. We assumed that a positive RDT indicated a recent clinical infection with *P. falciparum*. An efficacy estimate was calculated for each drug, defined as parasite clearance by microscopy. The overall crude weighted clearance rate was 36.8% for chloroquine, 43.2% for SP, 42.1% for quinine and 61.8% for ACT, but country-specific rates varied significantly. The estimate for ACT was significantly lower than that observed in clinical trials. In the DHS/MIS, 15.1% of those taking ACT did not adhere to treatment guidelines. Country-specific estimates of the proportion of poor quality drugs in private sectors were applied, which accounted for 8.3% of failures. A further 5% of failures is expected to stem from incorrect treatment recall. This study relies on self-reported data and it is difficult to estimate the extent to which incorrect recall influences efficacy estimates. Ongoing work aims to further quantify the proportion of treatment failure which is due to drug resistance, re-infection and other causes, and to obtain a burden estimate across Africa. Our analysis highlights that a large proportion of children continue to take non-ACT antimalarials for malaria (11.0% and 5.5% of infected febrile children taking chloroquine and SP respectively) and the associated failure rate is approximately 1.5-2 times higher than ACTs. These results highlight the urgency of improving ACT access across Africa.

1748

REAL-TIME PCR ASSAYS FOR THE DETECTION, SPECIATION AND QUANTIFICATION OF *PLASMODIUM FALCIPARUM, P. VIVAX, P. OVALE,* AND *P. MALARIAE*

David M. Rockabrand[1], Deborah Stiffler[1], Nathaniel Dizon[1], Alexander Iteen[1], Emily Parsons[1], Carolyne Kifude[2], Priya Venkatesan[1], Robin H. Miller[1], Shirley Luckhart[3], V. Ann Stewart[1]

[1]Uniformed Services University of the Health Sciences, Bethesda, MD, United States, [2]US Army Medical Research Directorate-Kenya (USAMRD-K)/

Kenya Medical Research Institute (KEMRI), Kisumu, Kenya, [3]University of Idaho, Moscow, ID, United States

The accurate diagnosis of malaria and the precise identification of the *Plasmodium* spp. is necessary for its successful treatment and eventual eradication. While microscopy or morphologic analysis continues to be the "gold standard" for malaria diagnosis, PCR assays are rapidly becoming the new standard alternative to microscopy. This molecular methodology has superior sensitivity and specificity and is becoming more common in the developing world or in otherwise resource limited environments. The *Plasmodium* species known to cause human malaria have varied and often overlapping geographical distributions that have yet to be fully characterized. The four predominant species, *P. falciparum*, *P. vivax, P. ovale,* and *P. malariae* are capable of mixed infections in both symptomatic and asymptomatic patients, with important ramifications in both public health and individual patient treatment. A mixed infection that includes *P. vivax* or *P. ovale* may be incompletely treated if blood-stage therapy is not immediately followed with primaquine. Incompletely treated patients could still serve as reservoirs of the disease, hindering local eradication efforts. qPCR has been used as a method of choice for detecting mixed infections. However, detection methods using sensitive primers and probes based on species-specific 18S rRNA often lack the specificity needed for accurate detection of low parasitemias. Herein, we describe a TaqMan-based qPCR assay using optimized primer and probe sets that lack homology among species and are specific for *P. falciparum (mls), P. vivax (ecpr), P. ovale (rbp2),* and *P. malariae (csp).* Validation experiments of the panel show a <10 copies/ul to 100,000 copies/ul detection range, even in the presence of high copy numbers of every other species detectible by the panel. The specificity of these assays is complete against the other species and contaminating human DNA. We characterize the limit of detection, limit of quantification, and specificity of each assay for use in a current study investigating *Plasmodium* species prevalence and mixed *Plasmodium* infections in HIV positive and negative populations in West Africa.

1749

FACTORS POTENTIALLY RESPONSIBLE FOR THE DECLINE OF MALARIA IN THE AYEYARWADY REGION OF MYANMAR

Myat M. Tun[1], Moe Moe Aye[2], Nan Aung[2], Christopher Lourenco[2], Arnaud Le Menach[2], Aung Thi[3], Jillian Dunning[2], Sarah Gallalee[2]

[1]Vector Borne Disease Control Program, Pathein, Myanmar, [2]Clinton Health Access Initiative, Boston, MA, United States, [3]National Malaria Control Program, Yangon, Myanmar

Although Myanmar has the highest burden of malaria in the Greater Mekong Subregion (GMS), the country has achieved an impressive 72% reduction in cases between 2012 and 2016 with a total of 110,146 reported cases in 2016. Myanmar is committed to eliminating falciparum malaria by 2025 and continued efforts are needed because of the threat of artemisinin resistance in the GMS. Understanding the factors that have led to a reduction in malaria burden can inform effective measures for future interventions in Myanmar, which can accelerate elimination efforts. The Ayeyarwady region of Myanmar provides a useful context for examining the reduction in cases; between 2012 and 2016, confirmed cases dropped from 21,782 to 5,525 (a 75% decrease). Trends in potential factors associated with malaria transmission including case management, vector control, surveillance, and ecological factors (e.g. deforestation) were examined in Ayeyarwady in order to assess the main drivers of decline in the region. Data from 2011-2016 were collected at the health facility level on the number of malaria tests performed, the number of confirmed cases reported, and health facility catchment populations. 2011-2016 data on bed net distributions and malaria specific Village Health Volunteer (VHV) placements were collected at the township level and two years at the village level. The results showed that between 2011 and 2016, the total number of tests conducted in Ayeyarwady increased 84% to a total of 105,661 tests in 2016. Also between 2011 and 2016, the number of VHVs increased from 50 to 467, and the tests performed by VHVs increased from 2,044 to 18,923. In townships with VHVs, the ABER increased from 16.7% in 2013 to 31.3% in 2016. LLINs have been distributed in Ayeyarwady since 2012, and between 2012 and 2016, an estimated 276,000 LLINs were distributed in the region. These trends in case management and vector control may have led to the reduction of malaria cases in Ayeyarwady; however, further analysis is required to assess these relationships and disentangle the roles of each potential factor.

1750

THE EMERGANCE OF *PLASMODIUM OVALE* IN KWANZA NORTE PROVINCE, ANGOLA

Mykola Babiuk[1], **Célio Njinga**[1], Borges Bongo[1], Rossely Paulo[2], Filipa Vaz[3], António Dikambo[4], Martins Franco[5]

[1]World Vision, Luanda, Angola, [2]CISA Health Research Centre of Angola, Luanda, Angola, [3]World Health Organization, Luanda, Angola, [4]Provincial Health Directorate of Kwanza Norte, Kwanza Norte, Angola, [5]National Directorate of Public Health, Luanda, Angola

Malaria in Angola is still the leading cause of mortality, morbidity and absenteeism at work and school, being endemic in the country's 18 provinces, with the highest transmission recorded in the northern provinces (Cabinda, Uige, Malange, Kwanza Norte, Lunda Norte and Lunda Sul)[1]. Moreover, it reflects about 35% of the demand for curative care, 20% of hospital admissions, 40% of perinatal deaths and 25% of maternal mortality. Malaria has not only a negative impact on the health of populations, but also on the economic and social development of them[1]. The fight against malaria is focused on the elimination of *Plasmodium falciparum* infections, which continues to be the main cause of malaria infection; whilst cases of *P. o*vale show an evolution from year to year. However, little is known about the degree of growth or decrease of *P. o*vale endemicity, with Kwanza Norte having a percentage of the affected population in the order of 28%, with a parasitemia index of 63% (Hiperendemic). Thus, 10 Municipalities were randomly selected and the population was randomly assigned to the Malaria Diagnostic Test, PRH2 / pLDH (pf/Pan) COMB Malaria, and afterwards the positive results were examined by microscopy, (Standard), obtaining the following results: *P. falciparum* (45%), *P. vivax* (0%), *P. ovale* (0.7%) and *P. malariae* (0.03%). Although the results show a rate (0.7%) within the National average[3], there is a gradual increase in the number of cases of infection with *P. o*vale, and in some municipalities rates are very high (eg. Golungo Alto, from 0% in year 1 to 24% in year 2). This result could be probably at least partly attributed to laboratory technicians lacking experience in reading the slides (for the correct identification of the strain) in the first year; for better understanding trends, it is important that RDTs are able to identify different antigens; the country must prepare itself with stocks of primaquine and equip the technicians with more training in order to prevent and when necessary, to handle cases that may arise. Finally, in species differentiation, including PCR Based Assay should be considered, in order to give greater robustness in the reliability of the results.

1751

EFFECTIVE COMMUNITY SURVEILLANCE REDUCES SEVERE MALARIA IN RURAL MADAGASCAR

Louisette Rahantanirina

JSI Research & Training Institute, Inc., Antananarivo, Madagascar

Malaria remains among the top four causes of death among children under five or CU5 in Madagascar. To reduce malaria infections among CU5, the USAID Community Capacity for Health Program supports community-based activities through community health volunteers or CHV in hard-to-reach communities in 7 of 22 regions of the country, reaching 6.1 million persons (23% of the population). These CHV were trained and equipped to provide integrated community case management services and disease surveillance activities including clinical management of febrile illness among CU5, active case finding in the community to ensure early diagnosis and treatment of malaria, and prompt, complete monthly reporting of data. CHVs also participated in investigation when analysis of

monthly reports revealed increases in malaria cases. We analyzed routine, community surveillance reports from 6,410 CHVs and key informant interviews during January 2017-February 2018. We explored the link between active action of CHV and deaths occurring of malaria. We found complete, timely reporting for 4707 CHVs. They correctly identified and treated 65,184 cases of malaria among CU5 in the community, and their reports contributed to detecting increases in malaria case reports in five districts, ranging from 2 to 30 cases per month per Fokontany. A total of 34 malaria-related deaths including 68% among CU5 were reported in these districts. Of these deaths, 94% had not been detected within 24 hours due to delayed communications and actions. We found that when CHV's contribution occurred within 24 hours, increases in malaria cases were mastered rapidly, avoiding deaths. Fewer cases of malaria related deaths (0-2 deaths) were then observed in the three districts of Antalaha, Manja, Soalala compared to the 2 districts of Besalampy, Boriziny where responses did not happen within 24 hours. We observed also a reduction of 44% malaria cases during the period. Community-based malaria intervention and surveillance may reduce treatment delays, improve outcomes and identify increases in malaria case reports more promptly, and should remain a key component of national malaria control strategy.

1752

COMMUNITY PERCEPTIONS ABOUT MALARIA RISK AND INFECTIONS IN A REGION OF HIGH MALARIA TRANSMISSION, WESTERN KENYA

Judith Nekesa Mangeni[1], Saran Indrani[2], Wendy P. OMeara[2], Andrew Obala[1]

[1]Moi University, Eldoret, Kenya, [2]Duke University, Durham, NC, United States

WHO recommends test - based management of malaria infections. Perceptions of the community on febrile illnesses and malaria test results determine the actual success of such guidelines. We conducted a prospective cohort study where an existing cohort of participants in three villages was followed up longitudinally. We report a subset of participants who underwent RDT testing. Requests for RDT testing were initiated by the participants if they felt unwell. During the visit, participants were asked behavioral questions and perceptions towards malaria. Participants who were found positive on RDT were treated with AL. A total of 330 visits were made in a period of 8 months for a total of 162 participants. We recorded 151(45.7%) episodes of malaria. Majority of the participants (130/162, 80.25%) believe that the presence of fever indicates the likelihood of malaria infection even if the RDT results are negative. Most of the participants rated their illness as moderate (79/162, 48.8%). Most of the participants (144/162, 89.4%) had a personal conviction that their illness was actually malaria. RDT test results, individual rating of severity of the illness and having a strong personal conviction that the illness is malaria (X^2 = 145, p<0.001, X^2= 54.5, P>0.001, X^2= 80.8, p <0.001 respectively) were strongly associated with perceptions on the likelihood of the illness being malaria. The community strongly perceives febrile illnesses as likely to be malaria infection despite a negative RDT test. However, overall perceptions on malaria infections are strongly associated with the test results. Successful efforts to reduce malaria in this region need to incorporate health education to correct misinformation.

1753

PLASMODIUM FALCIPARUM HAPLOTYPE INFERENCE FROM AMPLICON DEEP SEQUENCING TO IDENTIFY MICRO-SCALE PARASITE POPULATION MIXING

Kelsey M. Sumner[1], Steve M. Taylor[2], Elizabeth Freedman[2], Andrew Obala[3], Wendy Prudhomme O'Meara[4]

[1]University of North Carolina, Chapel Hill, NC, United States, [2]Duke University School of Medicine, Durham, NC, United States, [3]Moi University College of Health Sciences, Eldoret, Kenya, [4]Duke Global Health Institute, Durham, NC, United States

Consistently high *Plasmodium falciparum* malaria prevalence in Western Kenya enhances the need to understand how parasite spatial patterns influence disease transmission and targeted intervention effectiveness. Using a cross-sectional sample of 514 parasites from a 15km by 28km region in Bungoma East sub-county, Kenya, we assessed parasite population mixing across households using polymorphic *P. falciparum* genetic markers. We hypothesized that parasites separated by smaller geographic and temporal distance would be more closely related genetically; therefore, that we would observe increased parasite genetic divergence with larger spatial and temporal distance. To investigate these relationships, we used multiplex sequencing of three polymorphic *P. falciparum* gene segments encoding: 1) apical membrane antigen 1 (*ama1*), 2) circumsporozoite protein (*csp*), and a *Plasmodium* helical interspersed protein B (*PhistB*). Each gene target was amplified from field-collected polygenomic parasitemias and sequenced on an Illumina MiSeq; from these polymorphic reads, polyclonal parasite haplotypes were identified using the haplotype inference-calling program DADA2, as implemented in R, and population genetic analytic approaches were employed to quantify haplotype sharing and clustering on temporal and geographic scales. We found that there was variability in the participant-level *P. falciparum* haplotypes across the three gene targets, suggesting a spatial relation between participant household and parasite genetic divergence. Our results illustrated the feasibility of haplotype inference and the influence of parasite population mixing on a micro-scale.

1754

EXPANSION OF INSECTICIDE TREATED NETS OWNERSHIP ASSOCIATED WITH REDUCTION OF ALL-CAUSE CHILDHOOD MORTALITY IN KENYA, 2012 - 2014: EVIDENCE FROM INDIVIDUAL LEVEL ANALYSIS

Agneta Mbithi[1], Rebecca Kiptui[2], Hellen Gatakaa[1], Abdisalan Noor[3], Christie Hershey[4], Mildred Shieshia[5], Robert Perry[6], Waqo Erjesa[2], Yazoume Yé[7]

[1]MEASURE Evaluation, ICF, Nairobi, Kenya, [2]National Malaria Control Programme, Nairobi, Kenya, [3]KEMRI-Wellcome Trust Programme, Nairobi, Kenya, [4]United States Agency for International Development, President's Malaria Initiative, Washington, DC, United States, [5]United States Agency for International Development, President's Malaria Initiative, Nairobi, Kenya, [6]U.S. President's Malaria Initiative-Kenya, Malaria Branch, Division of Parasitic Diseases and Malaria, Center for Global Health, U.S. Centers for Disease Control and Prevention, Atlanta, GA, United States, [7]MEASURE Evaluation, ICF, Rockville, MD, United States

In the past decade, Kenya has expanded coverage of key malaria interventions, particularly insecticide treated nets (ITNs). There is evidence from ecological and trends analyses showing an association between the expansion of malaria interventions and the decline in all-cause child mortality (ACCM). Further evidence of association at the individual level will better inform the policies, strategies, and activities of Kenya's National Malaria Control Program and its partners. We assessed change in ACCM risk associated with ownership of ITN between 2012 and 2014 using the Kenya Demographic and Health Survey (DHS) 2014. We transformed women's full birth history data into 10-year retrospective longitudinal data reflecting individual child observations from birth until the date of the survey or loss to follow up (death). For each malaria endemic zone, we used a Cox proportional hazards model that included children ages 1 to 59 months for 24-month period of exposure to household ITN ownership (2012-2014). The model controls for several potential confounders. Nationally, household ownership of at least one ITN significantly reduced the risk of mortality among children aged 1 to 59 months by 56% (hazard ratio [HR]=0.44, 95% CI: 0.30-0.63) during the 24-month period before the survey. The protective effect was strongest in the Lake endemic zone, with mortality risk for children aged 1 to 59 months reduced by 72% (HR=0.28, 95% CI: 0.14-0.55). The Lake endemic zone had the highest

burden of malaria and highest ACCM rate throughout the evaluation period and thus the greatest potential to benefit from increased ITN coverage. This individual level analysis provides further evidence of the contribution of expanding ITN coverage to reducing ACCM among highest risk populations in Kenya.

1755

IRRIGATION AND MALARIA IN MALAWI: MALARIA INFECTION INTERACTS WITH POVERTY AT BWANJE VALLEY IRRIGATION SCHEME

Charles Mangani[1], Jobiba Chinkhumba[1], Grivin Chipula[2], Themba Mzilahowa[1], Don P. Mathanga[1], Edward D. Walker[3]

[1]University of Malawi College of Medicine, Blantyre, Malawi, [2]Lilongwe University of Agriculture and Natural Resources, Lilongwe, Malawi, [3]Michigan State University, East Lansing, MI, United States

Irrigation agriculture can increase productivity and household income in rural Africa. However, despite these socio-economic benefits, land transformation for irrigated agriculture may increase mosquito production, enhance malaria transmission, and undermine household productivity. To analyse the association between irrigation scheme participation, malaria and poverty, the following study was conducted in villages around Bwanje Valley Irrigation Scheme, a rice-growing cooperative of ca. 800 ha in Dedza District, Malawi. Three cross-sectional surveys were conducted at the end of the rainy seasons in April 2016, 2017, and during the dry season in November 2017. Socioeconomic, demographic, health and scheme participation data were collected. Blood samples were obtained for malaria rapid test and microscopic identification of *Plasmodium falciparum*. Assets quantified during surveys were used to categorize households into socioeconomic status (SES) with principal components analysis. 29% of households were active participants of the irrigation scheme. Among 5,131 individuals older than six months, prevalence of infection by microscopy was 30.7 % and was significantly higher in residents of households within a 3 km radius (33.2%) compared to 6 km from the scheme (25.9%). Prevalence declined with increasing household wealth quintile, showing an inverse association between malaria prevalence and SES, and declined with formal education. Analysis of 156 households visited during the first (baseline) and third surveys showed that 43.7% of households classified as poor at baseline transitioned into a higher SES by survey 3. Scheme participants were more likely than non-participants to progress to a higher SES (46.1% vs 42.8%). Among households classified into the highest SES at baseline, 44.8% regressed to a lower SES. Compared to scheme participants, non-scheme participants were more likely to regress into a lower SES: 47.2% vs 38.4%. Proximity of human residence to irrigation scheme and relative poverty increased malaria risk. Scheme participation may increase SES and increase likelihood of participants escaping poverty.

1756

UNDERSTANDING THE EPIDEMIOLOGY OF IMPORTED MALARIA CASES IN VIETNAM AMONG RETURNING INTERNATIONAL LABORERS

Kristina J. St. Clair[1], Kimberly A. Edgel[1], Sara E. Canavati[2], Thu M. Nguyen[2], Gerard C. Kelly[2], Thang D. Ngo[3], Tho H. Tran[3], Duong T. Tran[3], Thuy P. Nguyen[4], Nga Nguyen[4], Hoi T. Le[4], Trung V. Nguyen[4], Kinh V. Nguyen[4], Nicholas J. Martin[1]

[1]U.S. Naval Medical Research Unit No. 2, Singapore, Singapore, [2]Vysnova Partners, Inc., Bethesda, MD, United States, [3]National Institute of Malariology, Parasitology and Entomology, Hanoi, Vietnam, [4]National Hospital for Tropical Diseases, Hanoi, Vietnam

Vietnam has seen a 97% decline in malaria cases between 1991 and 2014, leading to a national goal of elimination by 2030. As local malaria transmission declines a greater focus on the importation and potential reintroduction of transmission is essential to support malaria elimination objectives. Challenges to elimination in Vietnam include an increasing risk of malaria importation through a growing labor force traveling to African and Southeast Asian countries, as well as the continued threat of multi-drug resistant malaria. Currently, little understanding exists on the epidemiology of imported malaria in Vietnam from returning international laborers. A study was conducted at the National Hospital of Tropical Diseases (NHTD) in Ha Noi in 2017 to 2018 to describe the clinical and epidemiologic characteristics of suspected malaria patients recently returning from Africa or Southeast Asia countries. Patients admitted to NHTD with a recent history of living or travelling abroad and exhibiting clinical symptoms of malaria were eligible participants. Travel histories, blood samples and clinical data were collected and analyzed. 31 participants were enrolled in the study. 87% (n=27) were males with a mean age of 36.5 years. 77% (n=24) reported to have had malaria at least once, with 16% (n=5) reporting to have had malaria more than 10 times. Angola (48%, n=15) and Cameroon (16%, n=5) were the most common countries visited. Work (68%, n=21) and business (16%, n=5) were the most common reasons for travel. 92% (n=29) tested positive for malaria by blood film examination, with 62% (n=18) diagnosed with *Plasmodium falciparum*. Day 3 parasite clearance rates were 50% (n=9) and 60% (n=3) for *P. falciparum* and *P. vivax* respectively. Data from these studies indicate that imported malaria from returning international laborers is a potential threat to elimination efforts in Vietnam that requires further attention. Additional scaled research and detailed investigation into appropriate malaria prevention and intervention strategies targeted towards international laborers, both at pre-departure and upon return is required.

1757

MALARIOMETRIC SURVEY IN GUINEA-BISSAU

David McGregor, Anna Last

London School of Hygiene & Tropical Medicine, London, United Kingdom

In 2015, the estimated *Plasmodium falciparum* mortality in Africa was 395 000 deaths. The World Health Organisation has called for a 90% reduction in malaria deaths by 2030. The Government of Guinea-Bissau is committed to eliminate malaria from the Bijagos Archipelago, a remote group of islands with limited access to medical care. The primary objective of this study was to map the *Pf* prevalence on Bubaque, the most populated island. A cross-sectional survey was performed during the peak transmission season of 2017. Participants were recruited using systematic random sampling in a stratified cluster design. *Pf* parasitaemia was detected using rapid diagnostic tests. Data on housing, education, larval source management, socio-economic status, anaemia and malaria preventive measures was collected from individuals and households via questionnaires. Multivariate logistic regression models were constructed to establish associations between these indicators and parasitaemia. 404 persons were included in the study. Prevalence of *Pf* parasitaemia was estimated to be 22.2% (95% CI: 18.7-26.0%). Persons aged 6 to 15 years had the highest odds of infection of all age groups compared to children of less than 1 year (OR 5.05, 95% CI: 1.01 – 25.12; p=0.04). Estimated prevalence of anaemia was 74.25% (95% CI: 69.04-78.85). All sampled houses were found to have open eaves. Bed net use was excellent with 99.5% of the population estimated to have slept under a net the night before the survey (95% CI: 97.8-99.9). Current malaria control programmes, such as bed net distribution and intermittent preventive treatment in pregnancy, are likely to be contributing to preventing *Pf* transmission on the island. It is recommended that the benefits of scaling up of malaria control programmes in conjunction with an intervention of mass drug administration using ivermectin and dihydroartemisinin-piperaquine be studied to reduce *Pf* transmission.

1758

PREVALENCE OF ASYMPTOMATIC AND SYMPTOMATIC MALARIA IN A REMOTE TRIBAL POPULATION OF ASSAM, NE INDIA

Laura Chery[1], Devojit K. Sarma[2], Kevin Gillespie[3], Ipsita Pal-Bhomick[2], Jennifer N. Maki[1], Khukumoni Bora[2], Dibya R. Bhattacharyya[2], Kanwar Narain[2], Jagadish Mahanta[2], James G. Kublin[3], Pradipsinh K. Rathod[1], Holly Janes[3], Pradyumna K. Mohapatra[2]

[1]University of Washington, Seattle, WA, United States, [2]Regional Medical Research Centre, NE Region (ICMR), Dibrugarh, India, [3]Fred Hutchinson Cancer Research Center, Seattle, WA, United States

In India, an estimated 1.24 billion people are at risk for malaria infection with over 160 million living in areas of high transmission. The northeast region of India is of particular interest due to higher prevalence rates, the predominance of *Plasmodium falciparum*, and its close proximity and ecological similarity to southeast Asia. A remote 7-village cluster in the Karbi-anglong district of Assam, India, was selected for a community-wide cross-sectional survey during the monsoon season (May-Sept) of 2015. 455 households received study visits, during which each resident was clinically assessed, tested for malaria by microscopy and RDT, and given a questionnaire about demographics and malaria knowledge and prevention practices. Identified malaria cases were referred for treatment per Indian National Drug Policy. Of the 2331 individuals surveyed, 152 (6.5%) were malaria positive; 143 (6.1%) with *P. falciparum*, 6 (0.3%) with *P. vivax* and 3 (0.1%) with mixed infection. The demographics of the villages were similar, though differences in prevalence of malaria were observed. The highest prevalence was in the village of Bhaktegaon (66/415; 15.9%). Among the population, there were slightly higher numbers of symptomatic (87, 3.6%) than asymptomatic (67, 2.9%) malaria. It was noted that while most (2233; 95.8%) individuals reported using a bed net, few (190; 8.5%) reported treated bed net usage. Treatment effectively cleared malaria parasites by day 7 in all but 3 individuals. Though the Government of India has committed to eliminating malaria by 2030, the low usage of treated bed nets (8.5%) and prevalence of symptomatic malaria (3.6%) indicate that routine prevention, diagnostic and treatment options may not be available or accessible to this population. The prevalence of asymptomatic malaria (2.9%) indicates a reservoir of malaria that may not be addressed by elimination efforts relying solely on identification and treatment of symptomatic individuals. Future work will focus on modeling the impact of targeting both symptomatic and asymptomatic infections and characterization of temporal changes in malaria prevalence within this population.

1759

MALARIA SURVEILLANCE FOR ELIMINATION: A PHASED ROLL OUT OF A CASE-BASED INFORMATION SYSTEM USING DHIS2 IN HONDURAS

Jose R. Pereira[1], Nely Romero[1], Carlos M. Herrera[1], Ricardo Valdes[1], Daniela Zuniga[1], Diana Nuñez[1], Nicolas Orlinder[1], Wilberto Montalvan[1], Ivan Espinoza[1], Seneyda Castañeda[1], Billy Gonzalez[1], Marco Pinel[1], Guillermo Aleman[1], Miguel Bobadilla[2], Jose R. Valdez[2], Tania Rivera[2], Luis M. Perez[3], Darlene Bhavnani[3], **Bricia G. Trejo**[3]

[1]Ministry of Health, Tegucigalpa, Honduras, [2]Global Communities, Tegucigalpa, Honduras, [3]Clinton Health Access Initiative, Boston, MA, United States

Honduras, characterized by highly focalized malaria transmission in its Northeastern region, reported 1,284 cases in 2017 and aims to eliminate malaria nationally by 2020. A previous surveillance system relied on paper forms to report malaria cases from the health facility to the department where they were electronically entered which has led to problems with completeness of data and reporting delays of up to one month. To ensure complete and timely reporting of case data by health facilities, the Ministry of Health implemented an electronic, centralized, case-based information system using District Health Information System 2 (DHIS2). In an initial phase starting in June 2017, information collected on paper during case notification and investigation was entered using Android tablets with DHIS2 Tracker Capture in 18 health facilities of two departments, Islas de la Bahia and Gracias a Dios. The feasibility of using electronic tools in health facilities with limited infrastructure and unreliable connectivity was evaluated through focus group discussion. Reporting rate (percent of paper forms entered in DHIS2) and timeliness (time between diagnosis and data entry into DHIS2) were estimated by reviewing paper versus electronic reports and information system logs. Between June and November 2017, 33 cases were reported into DHIS2 from Islas de la Bahia and 130 cases from Gracias a Dios. Ninety-five percent of paper reports were entered into DHIS2. The average time from malaria diagnosis to data entry into DHIS2 was 3 days in Islas de la Bahia and 11 days in Gracias a Dios. Findings suggest that there is high user acceptability and satisfaction with the new information system. However limited data entry staff and high staff turnover, especially in Gracias a Dios, remain a challenge for reporting rates and data timeliness. In 2018, Honduras will scale up health facility use of DHIS2 nationally. Simultaneously, Honduras will integrate additional data from laboratory, case management, entomological surveillance and vector control interventions, which will facilitate integrated analysis and decision making for malaria elimination.

1760

RISK FACTORS FOR MALARIA POSITIVITY AMONG FEBRILE CHILDREN AT FOUR HETEROGENEOUS KENYAN CLINICS

Melisa M. Shah[1], Amy R. Krystosik[2], Jamie M. Caldwell[3], Francis M. Mutuku[4], Bryson A. Ndenga[5], Victoria Otuka[5], Charles Ronga[5], Philip K. Chebii[6], Priscillah W. Maina[6], Zainab Jembe[7], Kelsey Ripp[8], Rashmi Vora[2], Prasanna Jagannathan[1], Desiree LaBeaud[2]

[1]Infectious Diseases and Geographic Medicine, Stanford University, Stanford, CA, United States, [2]Department of Pediatrics, Division of Infectious Disease, Stanford University, Stanford, CA, United States, [3]Department of Biology, Stanford University, Stanford, CA, United States, [4]Department of Environment and Health Sciences, Technical University of Mombasa, Mombasa, Kenya, [5]Kenya Medical Research Institute, Kisumu, Kenya, [6]Department of Pediatrics, Msambweni County Referral Hospital, Msambweni, Kenya, [7]Department of Pediatrics, Diani Health, Ukunda, Kenya, [8]Department of Medicine, Hospital of the University of Pennsylvania, Philadelphia, PA, United States

Clinic-based surveillance of febrile illness is an important metric for estimating malaria morbidity in Kenya where there is wide heterogeneity in malaria endemicity. To describe febrile illness in Kenyan children and risk factors for malaria, we collected comprehensive clinical, environmental, and sociodemographic data on a cohort of acutely ill febrile children less than 18 years of age at four heterogeneous outpatient clinical locations: two coastal clinics (Msambweni District Hospital and Ukunda Health Center) and two western clinics (Chulaimbo Health Center and Obama Children's Hospital in Kisumu). Among 4,608 febrile visits across the four clinical sites from 2014-2017, 50% of febrile children had malaria parasitemia by microscopy with significant differences by site (Chulaimbo 81%, Ukunda 52%, Msambweni 44%, Kisumu 43%, $p<0.001$). In univariate analyses, children with malaria were more likely to report mosquito bites in the last four weeks, were older (6.2 years versus 5.6 years) and reported lower socio-economic status compared to children without malaria. In multivariate logistic analysis controlling for age, sex, site, socioeconomic status, rainfall, and mosquito exposure, odds of malaria infection decreased by 30% when mean daily environmental temperature increased above 26.5°C compared to 22-26.5°C. In the same model, the odds of malaria parasitemia decreased by 11% among those reporting cough at acute infection and increased by 16% if nausea or vomiting was reported. In site specific multivariate models, children reporting mosquito bites in the 4 weeks prior had a 1.69 increased odds of malaria in Chulaimbo; odds of malaria increased by 19% among children

10-15 years of age compared to children 0-5 years of age in Msambweni. By characterizing risk factors for malaria positivity, this study will facilitate improved care of febrile Kenyan children and targeted interventions by clinic type.

1761

ASSESSING COMMUNITY HEALTH WORKER PERFORMANCE FROM ROUTINE DATA

Caitlin A. Bever[1], John M. Miller[2], Kammerle Schneider[3], Busiku Hamainza[4], Michael Hainsworth[3], Maya Fraser[3], Edward Wenger[1]

[1]Institute for Disease Modeling, Bellevue, WA, United States, [2]PATH MACEPA, Lusaka, Zambia, [3]PATH MACEPA, Seattle, WA, United States, [4]National Malaria Elimination Centre, Lusaka, Zambia

Routine data collected in the health system forms the backbone of surveillance in malaria control and elimination programs. In many areas, programs are turning to community-based case management to improve access by decreasing the distance to a point of care. When case investigation or reactive case detection (RCD) is implemented, community health workers (CHWs) are often tasked with these responsibilities in addition to their regular caseload. To ensure high-quality implementation, it is important to assess whether CHWs are carrying out RCD to protocol and to flag individual CHWs who may be overburdened with treating index cases or otherwise underperforming so that program managers can rectify these issues. We present a simple methodology for using routine data collected by CHWs as part of their activities to assess CHW performance. This method is applied to health facility catchment areas in Southern Province, Zambia, where RCD activities began in 2014. We identify catchments where CHW performance clearly improved over the last few years and other areas where performance is still an issue, particularly during the wet season. This framework is flexible and easily extendable to any RCD implementation where a few basic health care metrics are collected.

1762

TRENDS IN ITN, IPTP-SP USAGE AND MALARIA PREVALENCE AND ANEMIA IN PREGNANT WOMEN ON BIOKO ISLAND, EQUATORIAL GUINEA

Norberto Bosepa Cubacuba[1], Gninoussa Akadiri[1], Godwin Fuseini[1], Wonder Philip Phiri[1], Matilde Riloha Rivas[2], Carlos Cortes Falla[1], Christopher Schwabe[3], Guillermo Garcia[3]

[1]Medical Care Development International, Malabo, Equatorial Guinea, [2]Ministry of Health and Social Welfare, Malabo, Equatorial Guinea, [3]Medical Care Development International, Silver Spring, MD, United States

The World Health Organization (WHO) recommends and emphasizes the use of insecticide treated bednets (ITNs) and intermittent preventive treatment (IPT) for all pregnant women in areas of stable transmission of *Plasmodium falciparum* malaria. The Bioko Island Malaria Control Project (BIMCP) in partnership with the Ministry of Health and Social Welfare of Equatorial Guinea aims at increasing the proportion of pregnant women sleeping under ITNs and receiving IPT with Sulphadoxine-pyramethamine (SP). This study examined the coverage of these interventions among pregnant women on Bioko Island and the optimal protection they confer against malaria and anaemia. Long-lasting insecticidal nets (LLINs) are distributed to pregnant women at public health facilities during antenatal care visits. The first dose of IPT-SP is administered through directly observed therapy (DOT) during the second trimester of gestation. Malaria education is also provided to women during antenatal care visits. The BIMCP conducts annual cross-sectional Malaria Indicator Surveys (MIS) on Bioko Island to determine malaria prevalence and anaemia. In 2014, the number of pregnant women who slept under ITNs was 19.3%. This increased to 53.5% in 2015 following a mass distribution campaign, but later dropped to 36.8% in 2016. The percentage of pregnant women who received at least one dose of IPT-SP during their pregnancy remained stable from 2014 to 2016 (79.8% in 2014, 73.6% in 2015 and 73.4% in 2016). However, 22.7% took three or more doses in 2014. This increased to 37.2% in 2015 and more than doubled to 64.7% in 2016. *P. falciparum* parasitemia among pregnant women was 11.5% in 2014, which dropped to 10.5% in 2015 and further to 5.2% in 2016. Moderate/severe anaemia among women was 3.2% in 2014, 3.4% in 2015 and 1.5% in 2016. The substantial increases in the consumption of three or more doses of IPT-SP during pregnancy could have contributed to the reduction of *P. falciparum* parasitemia and moderate/severe anaemia among pregnant women on Bioko Island.

1763

EARLY FOCAL MALARIA UPSURGE DETECTION AND RESPONSE IN KISORO, A LOW TRANSMISSION, UNSTABLE MALARIA SETTING OF UGANDA

Damian Rutaazana[1], **Daniel J. Kyabayinze**[1], Godfrey Muntu[1], Edward Mugwanya[2], Stephen Nsabiyumva[3], Jimmy Opigo[1]

[1]National Malaria Control Programme, Kampala, Uganda, [2]RHITE SW, Kisoro, Uganda, [3]Kisoro District Local government, Kisoro, Uganda

Areas with unstable malaria transmission are prone to epidemics and these upsurges in malaria cases should be dealt with promptly. The use of information derived from a quality surveillance system to inform targeted delivery of effective malaria interventions, has provided tools for malaria upsurge detection Kisoro Uganda. We reviewed lessons from the Kisoro district led response to a malaria epidemic. Between January and March 2018, the data was collected and analysed from Health information records, DHIS2, reviewed supervision reports from the district health Team, partners and National Malaria Control Program. The review and analysis was part of the comprehensive response to the malaria upsurge detected in Kisoro district. Analysis of DHIS2 data by Kisoro district showed a 3-fold increase in Malaria cases from week 46 to 51, 2017. The Malaria Test positivity rate increased from 20% to 50. The upsurge was localized in the sub-counties of Murora and Kanaba, bordering the Sereri and Mpundu swamp. Entomological assessment showed increased density of *Anopheles gambiae sensu lato* mosquitoes, breeding in the swamp. The district activated the taskforce on detection of the epidemic and responded within one week. The response measures included community sensitisation, restocking medical supplies, outreach screen and treatment, surveillance, tracking and weekly reporting. The Malaria cases reduced by 50% in a period of 12 weeks district led response. Capacity to detect and respond to epidemics exists at district level but this needs to be enhanced to ensure timely and adequate supplies including training and provision of as antimalarial buffer stock. Focal larval source management or Indoor residual spraying would be a suitable intervention for this setting.

EARLY DETECTION OF MALARIA UPSURGES AT SUB-NATIONAL LEVELS IN UGANDA

Paul Mbaka[1], **Daniel J. Kyabayinze**[2], Damian Rutaazana[2], Jimmy Opigo[2]

[1]World Health Organization, Kampala, Uganda, [2]National Malaria Control Programme, Kampala, Uganda

The World Health Organization (WHO) has set specific targets for early detection and control of malaria epidemics as part of a wider strategy to cut the global extent of malaria in half by 2030 (1). In mid-2015, a malaria upsurge was detected in the northern part of Uganda following withdrawal of indoor residual spraying (IRS). As part of the response, ministry of health developed a weekly malaria case monitoring system as a surveillance tool in Uganda. We performed a document review of weekly malaria status reports produced by the Uganda national malaria control programme (NMCP) between January 2016 and December 2017 to assess their effectiveness as a malaria upsurge detection tool. During the period under review, 60/96 (63%) weekly malaria updates were generated. In this same period, a total of 51/122(42%) districts reported surge in malaria cases. Of these, 8 were high, 41 moderate and 2 low transmission,

compared no such report in 2013 and 2014. One of the upsurge was detected in Kisoro, a district with unstable malaria with parasite prevalence < 5%. The status updates also presented details of testing rates, malaria supply status and mortality surveillance. Though limited response to recommendations made in the weekly reports were observed, the reports provided clear and concise recommendation and some of them reported status of implementation of recommendations. Continuous review of district based data is an appropriate tool for early detection of malaria upsurges. An observed limitation was the detection of surges at district albeit too late rather than at sub-district level where actual early detection and response is possible.

1765

IMPROVING THE USE OF MALARIA SURVEILLANCE DATA FOR COUNTY LEVEL DECISION-MAKING BY ADDRESSING GAPS IN DATA SUPPLY AND BARRIERS TO DATA DEMAND IN KENYA

James Njeru[1], Patrick Njoka[2], Henry Muinde[3], Luke Baertlein[1], Rebecca Goldstein[1], Deepa Pindolia[1], Patricia Njiri[1]

[1]Clinton Health Access Initiative, Nairobi, Kenya, [2]Narok County Malaria Control Program, Narok, Kenya, [3]Kitui County Malaria Control Program, Kitui, Kenya

While there have been significant reductions in the malaria burden in the past decade, malaria transmission in Kenya remains endemic and heterogeneous across the country. Gaps in the national surveillance system, specifically with regard to data-informed programmatic decision making at sub-national levels, hinders further progress towards malaria elimination. To comprehensively address gaps in data supply (data collection, reporting and analysis) and data demand (data use for decisions) Clinton Health Access Initiative engaged with health management teams in Narok and Kitui counties to implement a set of targeted interventions between 2016 and 2018. Data supply interventions included ensuring all health facilities had reporting registers stocked, training of health care workers, and a review of surveillance practices during supervision visits from sub-county health management teams (SCHMTs). A dashboard was developed to ensure availability and accessibility of relevant analyses of key indicators tailored to SCHMTs needs. To improve data demand and use, a quarterly series of data review meetings were held to build capacity for and a culture of using surveillance data for evidence-based decision making among SCHMTs. Improvements in data supply included increased health facility reporting rates, from 70% in Q1 2016 to 89% in Q1 2018, improved feedback to facilities on data collection and reporting, and closer monitoring of surveillance data quality by sub-county health records officers. Data demand was improved through data review meetings by building capacity and skills among SCHMTs while facilitating dialogue around interpretation and use of data to target and plan programmatic activities. Anticipated long-term outcomes include sustained improvements in data collection and reporting among health facilities and in use of data among SCHMTs. Use of data to guide programmatic decision-making is expected to lead to more efficient and effective allocation of resources and overall improvement in malaria case management and prevention. A more detailed impact evaluation of this process will inform potential national scale-up.

1766

HUMORAL IMMUNE RESPONSES AGAINST THE MALARIA VACCINE CANDIDATE ANTIGEN *PLASMODIUM VIVAX* CSP AND *IL-1* PLUS *IL-2* GENE POLYMORPHISMS IN INDIVIDUALS LIVING IN AN ENDEMIC AREA OF THE BRAZILIAN AMAZON

Marcela P. Capobianco[1], Gustavo C. Cassiano[2], Adriana A. Furini[3], Luciane M. Melo[4], Tamirys S. Pimenta[5], Ana Paula D. Rodrigues[6], José Eduardo G. Arruda[5], Andrea R. Baptista[7], Joseli Oliveira-Ferreira[8], Claudia R. Bonini-Domingos[1], **Ricardo L. Machado**[7]

[1]IBILCE/UNESP, São José do Rio Preto, Brazil, [2]UNICAMP, Campinas, Brazil, [3]UNIRP, São José do Rio Preto, Brazil, [4]Universidade Federal do Sergipe, Aracaju, Brazil, [5]Universidade Federal do Pará, Belém, Brazil, [6]Instituto Evandro Chagas, Ananindeua, Brazil, [7]Universidade Federal Fluminense, Niteroi, Brazil, [8]FIOCRUZ/RJ, Rio de Janeiro, Brazil

It is well established that infection by *Plasmodium vivax* is a result of host-parasite interactions. This study evaluated polymorphisms in the *IL1* and *IL2* genes and of the central portion of the circumsporozoite protein (CSP) and correlated them with the cytokine profiles, anti-CSP antibody levels and parasitic loads of 138 individuals naturally infected with *P. vivax* in an endemic area of the Brazilian Amazon. *Methods: IL1B -511C>T*, *IL2 -330T>G* and *IL2 +114T>G* polymorphisms were identified using PCR-RFLP and allele-specific PCR. IL-1β and IL-2 cytokine levels were detected by flow cytometry. CSP antibodies were measured by ELISA. The prevalence and magnitude of IgG antibodies were higher for the VK210 variant. Significant differences were observed between SNP -511T>C in the *IL1B* gene and levels of antibodies to the VK247 and *P. vivax*-like variants, but there were no associations between SNPs in genes *IL1* and *IL2* and their plasma products. Studies of associations of cytokine gene SNPs in the humoral immune response to malaria are still incomplete, and the results have been contradictory. Given that the evolution of malaria results from the interaction of factors inherent to both parasite and host, this study helped to identify genetic variants that may influence the humoral immune response against malaria, particularly *P. vivax*.

1767

TAKING MALARIA GENOMIC TECHNOLOGY TO THE FIELD: A TWO-STEP PROTOCOL OF SELECTIVE WHOLE GENOME AMPLIFICATION AND TARGETED AMPLICON DEEP SEQUENCING (SWGA-TADS) FOR CHARACTERIZING LOW PARASITAEMIA AND LOW QUALITY *P. FALCIPARUM* INFECTIONS

Andreea Waltmann[1], Travis Fulton[1], Ulrika Morris[2], Andreas Märtensson[3], Billy Ngasala[4], Anders Bjorkman[2], Steven R. Meshnick[5], Jonathan J. Juliano[5]

[1]Institute of Global Health and Infectious Diseases, University of North Carolina Chapel Hill, Chapel Hill, NC, United States, [2]Karolinska Institute, Stokholm, Sweden, [3]Department of Women's and Children's Health, International Maternal and Child Health, Uppsala University, Uppsala, Sweden, [4]Department of Parasitology and Medical Entomology, School of Public Health, Muhimbili University of Health and Allied Sciences, Dar es Salaam, United Republic of Tanzania, [5]Division of Infectious Diseases and Department of Epidemiology, Gillings School of Global Public Health, University of North Carolina Chapel Hill, Chapel Hill, NC, United States

It is difficult to obtain sufficient malaria DNA for sequencing from field samples that are poor quality or low parasitemia (<50 parasites/microliter). Selective whole genome amplification (sWGA) is an effective tool to enrich the target DNA relative to high levels of contaminating host DNA for sequencing microorganisms. However, it remains limited in its ability to allow for whole genome sequencing from infections of low parasitaemia (<50 parasites per microliter) and in field samples whose quality and suitability for genomic studies are questionable. In order to allow for targeted genotyping of these poor-quality malaria field samples, we investigated a two-step protocol of sWGA coupled with amplicon

deep sequencing. Amplicon deep sequencing was performed used the highly-variable apical membrane antigen 1 (AMA1) as the target, a widely used *P. falciparum* genotyping marker. We validated the approach using mock mixtures of laboratory *P. falciparum* strains with the following characteristics: ***i)*** low starting DNA concentration commonly seen in low-parasitaemia infections (0.01 ng/mL = ~3.5x10^2 genome copies/mL and 0.001 ng/mL = ~3.5x10 genome copies/mL); ***ii)*** varying complexities of infection (three mock mixtures of MOI=1, 3 and 5) and ***iii)*** with uneven within-sample frequencies (MOI=1: 3D7 100%; MOI=3: FCR3 85.5% + DD2 10.5% + 3D7 4.0%; MOI=5: 7G8 50.0% +FCR3 25.0% +3D7 15.0% +DD2 5.0% +HB3 5.0%). In addition, to test for the role contaminating human DNA has on protocol efficacy, three other mixtures were also made by spiking the MOI=3 *P. falciparum* mixture above with human DNA to obtain 10% parasite DNA and 90% human DNA. Finally, the protocol was then tested on clinical DNA samples extracted from *P. falciparum*-positive rapid diagnostic tests (RDTs) collected from Zanzibar, a low transmission setting where low density infections are common. Our findings suggest that a two-step protocol comprising sWGA and amplicon deep sequencing is a reliable and scalable technology which overcomes issues of low parasitaemia and low sample quality issues and allows accurate deep sequencing characterization of otherwise unsuitable field samples.

GENETIC EVIDENCE OF CLONAL SPREAD, PARASITE EXCHANGE, AND UNIQUE SIGNATURES OF RELATEDNESS AMONG *PLASMODIUM FALCIPARUM* SAMPLES FROM HAITI

Rachel Fath Daniels[1], Seth Redmond[1], Stella Chenet[2], Eric Rogier[2], Curtis S. Huber[2], Camelia Herman[3], Baby Pierre[4], Jean Frantz Lemoine[4], Jacques Boncy[4], Daniel E. Neafsey[1], Michelle Chang[5], Dyann F. Wirth[1], Venkatachalam Udhayakumar[2], Sarah K. Volkman[1]

[1]Harvard TH Chan School of Public Health, Boston, MA, United States, [2]Malaria Branch, Division of Parasitic Diseases and Malaria, Center for Global Health, Centers for Disease Control and Prevention, Atlanta, GA, United States, [3]CDC Foundation, Atlanta, GA, United States, [4]Programme National de Contrôle de la Malaria, Ministère de la Santé Publique et de la Population, Port-au-Prince, Haiti, [5]Malaria Branch, Division of Parasitic Diseases and Malaria, Center for Global Health, Centers for Disease Control and Prevention, Atlanta, GA, United States

Haiti is one of the last countries in the Caribbean with continued malaria transmission; thus, there is great interest in malaria elimination in this region. While much of the population of Haiti is at risk for malaria, there are a limited number of cases (17,622 in 2016), making conventional epidemiological measures such as case incidence and prevalence challenging. In this context, genetic signals are useful for the identification and characterization of the *Plasmodium falciparum* parasite population to identify *Foci* of transmission, detect outbreaks, and track parasite movement to inform elimination efforts. We evaluated 470 single-genome *P. falciparum* DNA samples extracted from dried blood spots from malaria-positive patients reporting to health facilities from primarily three Haitian departments (Nippes, Grand'Anse, and Sud). Initial genetic assessment using a 21-single-nucleotide polymorphism molecular barcode revealed evidence of clonal expansion within Nippes, in which 158/170 samples were an identical barcode type, as well as the divergence of a single clonal type in Grand'Anse. Furthermore, we detected the exchange of nine parasite lineages between Nippes, Sud, and Grand'Anse. In addition, 460/470 samples shared high levels of genetic similarity with at least one other sample in the dataset within 44 barcode-identical clusters. Based on this initial identification of a highly-related parasite population, we sought to further assess the relatedness of the parasites in these clusters. We performed whole-genome next-generation sequencing to characterize parasite relatedness as the percent of the genome shared between parasites as well as the length of stretches of genomes that were considered identical-by-descent. The results revealed patterns of relatedness suggestive of repeated recombination of a limited number of founding parasite types without significant outcrossing. These genetic signals offer glimpses of the underlying relatedness of parasite populations and may be used to identify *Foci* of transmission against which targeted control efforts may be applied towards the elimination of malaria in Haiti.

1769

PROBABILISTIC CLASSIFICATION OF *PLASMODIUM VIVAX* RELAPSE AND REINFECTION USING MICROSATELLITE GENOTYPING DATA FOR IMPROVED ESTIMATION OF RADICAL CURATIVE EFFICACY

Aimee R. Taylor[1], James Watson[2], Caroline O. Buckee[1], Mallika Imwong[2], Cindy S. Chu[2], Nicholas J. White[2]

[1]Harvard T.H. Chan School of Public Health, Boston, MA, United States, [2]Mahidol Oxford Tropical Medicine Research Unit, Bangkok, Thailand

Plasmodium vivax is a major cause of malaria outside Sub-Saharan Africa. Vivax malaria is characterized by repeated relapses which arise when formerly dormant liver hypnozoites are reactivated, leading to blood-stage infections. Relapse causes significant morbidity. The inability to distinguish relapse from reinfection hinders the assessment of antimalarial drug efficacy. Accurate estimation of radical curative efficacy therefore requires a probabilistic distinction of relapse from reinfection. We have a developed a Bayesian framework for the probabilistic classification of recurrent vivax infections using polymorphic microsatellite markers. This method was applied to data from a randomized control trial comparing two primaquine radical cure regimens, and jointly models time-to-recurrence and *P. vivax* genetic data on nine microsatellite markers. A model of time-to-recurrence provides the prior probability. The genetic likelihood component integrates over all possible parasite relatedness networks within and across infections. We use a simplified model of identity by descent (IBD), whereby relapsing parasites can be clones (IBD of 1), meiotic siblings (IBD of 0.5), or strangers (IBD of 0), whereas parasites derived directly from reinfection are assumed to be strangers (IBD of 0). Preliminary results suggest that the efficacy of primaquine radical cure is greater than suggested from current standard clinical trial reports, with over 80% of recurrent infections following radical cure having a high probability of being reinfections rather than relapses. The day 7 carboxy-primaquine concentration (a slowly eliminated inactive metabolite) was a weak predictor of treatment failure (relapse). Probabilistic classification of relapse and reinfection significantly improves the estimation of the efficacy of radical curative regimens for vivax malaria. This method can be applied to radical cure efficacy trial data and, importantly, to other applications where the inability to distinguish relapse from reinfection presents a major challenge (e.g. to estimate incidence for the evaluation of intervention measures).

POPULATION GENOMICS OF VIVAX MALARIA IN THE GREATER MEKONG SUBREGION

Awtum M. Brashear[1], Qi Fan[2], Liwang Cui[1]

[1]Pennsylvania State University, University Park, PA, United States, [2]Dalian Instititute of Technology, Laoning, China

Quick evolution and notable diversity in the genus *Plasmodium* has made effective drug, vaccine and diagnostic design a major hurdle to Malaria eradication. Further, it necessitates regional eradication programs tailored to specific Malaria populations. *Plasmodium vivax (Pv)* is the most common malarial pathogen outside of Africa, including in the Greater Mekong Subregion (GMS). Out of the 6 GMS countries, Myanmar has the highest documented Malaria burden, but very little is known about specific malaria populations in Myanmar, or the spread of *Pv* to and from nearby countries. In the past, population analyses for *Pv* in Myanmar and on its Chinese border have been limited by sample availability, among other factors. Using next generation sequencing data from *Pv* field isolates, we've addressed *Pv* variation around the China-Myanmar border both at

the whole genome level and within individual genes of functional interest. Continuing analysis will expand these results to other parts of the GMS and guide local Malaria eradication efforts.

EUPATHDB: FREE, ONLINE OMICS RESOURCES FOR EUKARYOTIC PATHOGENS

Susanne Warrenfeltz[1], Brian Brunk[2], Omar Harb[2], Jessica Kissinger[1], David Roos[2]

[1]University of Georgia, Athens, GA, United States, [2]University of Pennsylvania, Philadelphia, PA, United States

The Eukaryotic Pathogen Database (EuPathDB, http://eupathdb.org) is a free, online data mining resource supporting over 190 organisms within Amoebazoa, Apicomplexa, Chromerida, Diplomadida, Trichomonadida, Kinetoplastida and numerous phyla of oomycetes and fungi. EuPathDB facilitates the discovery of meaningful biological relationships from large volumes of data by integrating pre-analyzed Omics data with advanced search capabilities, data visualization and analysis tools. The intuitive graphic interface allows users to take full advantage of the data without the need for computational training. EuPathDB integrates a wide range of data including genome sequence and annotation, transcriptomics, proteomics, epigenomics, metabolomics, population resequencing, clinical data, and host-pathogen interactions. Data are analyzed using standard bioinformatics workflows and an in-house analysis pipeline generates data including domain predictions and orthology profiles across all genomes. EuPathDB offers several perspectives for data mining - record pages which compile all data for genes, pathways, study subjects, etc; a genome browser for visualizing sequence data aligned to a reference genome; a search strategy system for querying pre-analyzed data to find genes or features that share biological characteristics, and a private workspace for analyzing primary data (via a Galaxy interface) and viewing the results in context with public data already integrated into EuPathDB. This free, comprehensive data mining resource easily merges evidence from diverse data types and across organisms to place the power of bioinformatics with the entire scientific community. EuPathDB's active user support offers an email help desk, social media, a You Tube channel and a worldwide program of workshops. Please stop by our booth in the exhibit hall or our poster for a demonstration, to suggest a data set or see our newest addition, ClinEpiDB (http://clinepidb.org) which facilitates the exploration and analysis of epidemiologic studies.

REPEATED INDOOR RESIDUAL SPRAYING REDUCES *PLASMODIUM FALCIPARUM* EFFECTIVE POPULATION SIZE AND INCREASES INBREEDING IN A VERY HIGH TRANSMISSION AREA OF UGANDA

Sofonias K Tessema[1], John Rek[2], Anna Chen[1], Noam Teyssier[1], Yoon Lee[1], Emmanuel Arinaitwe[2], Joaniter I. Nankabirwa[2], Sarah G. Staedke[3], Moses R. Kamya[4], Grant Dorsey[1], Isabel Rodriguez-Barraquer[1], Bryan Greenhouse[1]

[1]Department of Medicine, San Francisco General Hospital, University of California, San Francisco, CA, United States, [2]Infectious Diseases Research Collaboration, Kampala, Uganda, [3]London School of Hygiene & Tropical Medicine, London, United Kingdom, [4]Department of Medicine, Makerere University College of Health Sciences, Kampala, Uganda

The recent reduction in malaria mortality and morbidity in Africa has been primarily attributed to vector control interventions, including long-lasting insecticidal nets (LLINs) and indoor residual spraying of insecticide (IRS). These control programs, if successful, reduce the size of circulating *plasmodium* populations. Measuring population genetic parameters may provide insight into the effect of these interventions on transmission and the parasite reservoir. In this study, we used samples from a longitudinal study conducted in Nagongera, Uganda where universal LLINs distributed in 2013 did not reduce the incidence of malaria but IRS starting in late 2014 had a dramatic reduction (3.25 cases per person year pre-IRS versus 0.63 post-IRS). Samples from 393 *Plasmodium falciparum* infections in 196 children, collected in four distinct time periods were genotyped using 25 microsatellite markers. The time periods considered were: pre-ITN and –IRS; post-ITN and pre-IRS; post-2nd round IRS and post-3rd round IRS. No significant changes were observed in any population genetic parameters after LLINs. However, the frequency of infections containing multiple parasite genotypes decreased following IRS (87% pre-IRS to 67% post-IRS, $p < 0.0001$). The most striking change was the significant decline in the genetic diversity (H_E) of parasites (mean H_E, 0.72 ± 0.01 pre-IRS to 0.66 ± 0.02 post-IRS, $p = 0.004$). Furthermore, the effective parasite population size (*Ne*, 16872 pre-IRS vs 6656 post-IRS, $p < 0.001$) was significantly reduced. The reduction in population size was associated with a 2.6-fold increase in linkage disequilibrium and a 10-fold increase in the proportion of sampled infections which were closely related to each other. These findings suggest that, even in areas of extremely high transmission, effective IRS can significantly reduce the parasite reservoir and decrease the opportunity for outbreeding. This study also illustrates how genetic data can complement epidemiological surveillance, providing support for the utility of genetic parameters to measure changes in transmission intensity and asses the efficacy of interventions.

1773

EVALUATION OF AMPLICON SEQUENCING ON MOCK COMPLEX *PLASMODIUM FALCIPARUM* INFECTIONS

Timothy M. Farrell[1], Angela M. Early[1], Rachel F. Daniels[1], Sarah K. Volkman[2], Dyann F. Wirth[2], Bronwyn L. MacInnis[1], Daniel E. Neafsey[2]

[1]The Broad Institute of Harvard and Massachusetts Institute of Technology Boston, MA, United States, [2]Department of Immunology and Infectious Diseases, Harvard T. H. Chan School of Public Health, Boston, MA, United States

Accurate genotyping of complex (polyclonal) malaria infections is important for assessing population-level effects of interventions over geography and time. Amplicon sequencing is a cost-effective, high-throughput genotyping technology, but its data can be subject to technical artifacts, especially when applied to difficult-to-sequence genomes like *P. falciparum*. In addition, traditional tools for amplicon data quality control, which utilize low-resolution classification against known sequences (e.g. 16S databases), are inadequate when single-base haplotypic differentiation is desirable. We evaluated the performance of several existing amplicon sequencing analysis pipelines on data generated for amplicons in *CSP* and *SERA2* from a set of known samples with differing genotype compositions at low parasite densities (1-200 parasites per µl). Using a simple clustering approach that ignores variants in pre-identified homopolymeric regions, our analysis pipeline achieved high overall sensitivity and positive predictive value (0.80 ± 0.098 ROC area-under-curve), meeting or exceeding the performance of comparable pipelines (DADA2, SeekDeep and HaplotypeR). As expected, we saw significant performance gains at high versus low parasite densities (0.88 vs. 0.75 at > 20 parasites/µl and < 20 parasites/µl, respectively). We also observed high concordance between genotype frequency predictions of the two most performant tools (r^2: 0.92, $P < 1.0e-100$), despite the fact that these predictions agreed less precisely with expectation (r^2: 0.55, $P = 3.3e-52$). This suggests that inaccuracies when assessing sample genotype ratios may result from disproportional amplification during PCR and sequencing, particularly at low parasite densities, rather than the analytical methods themselves. We present a well-evaluated, highly-scalable amplicon sequencing analysis pipeline and make it freely available for use on FireCloud, a cloud computing service for genomic analysis workflows.

1774

TARGETED DEEP SEQUENCING OF MALARIA INFECTIONS IMMEDIATELY POOLED AT COLLECTION TIME EFFICIENTLY PROVIDES ACCURATE FREQUENCIES OF DRUG RESISTANCE MUTATIONS IN GHANA

Anita Ghansah

Noguchi Memorial Institute for Medical Research, University of Ghana, Legon, Ghana

Some major challenges to surveillance of antimalarial resistance in sub-Saharan Africa are logistical and financial challenges, limiting its breadth and frequency. Rapid inexpensive methods are therefore needed to monitor antimalarial drug resistance. We present a streamlined process of creating a singular sample immediately pooled (ipool) at collection time followed by high-throughput targeted sequencing using molecular inversion probes. Ten malaria control sentinel sites have been targeted across Ghana for this study. 50ul of each RDT or microscopy malaria positive sample obtained from patients of all ages during routine malaria testing were ejected into a growing pool in a 15ml falcon tube containing 4 ml of DNA/RNA shield to preserve the sample. In all, a pool of a mixture of 100 sequential *P. falciparum* infections was prepared by the laboratory technician at each site and stored at 4°C until ready for DNA extraction. Individual dried blood spots (DBSs) were also prepared on filter papers. Genomic DNA was extracted from ipools and DBSs. Molecular inversion oligonucleotide probes designed to capture known and candidate drug resistance mutations in p*fcrt*, p*fmdr1*, p*fdhfr*, p*fdhps*, as well as span entire length of *pfK13* were used in capture reactions and subsequent sequencing on the MiSeq platform. Our initial results from 2 sites, Cape Coast and Begoro indicate a 99% correlation between prevalence of drug resistance markers estimated from individual patients and the frequency of mutations measured from the ipool samples. Our study validates the ipool method as a cost-efficient, accurate and highly scalable approach for drug resistance monitoring. Our approach to resistance monitoring minimizes the burden on the clinical and public health systems by collecting and processing pools of individuals rather than each individual patient. For *P. falciparum* malaria this will allow us to quantitatively determine mutation frequencies within the pooled mixture of individual infections at numerous locations and multiple times per year moving towards providing fine resolution mapping and tracking of drug resistance across Ghana near real-time.

1775

QUANTIFYING POPULATION STRUCTURE OF MALARIA PARASITES USING EPIDEMIOLOGICAL AND GENOMIC DATA

Hsiao-Han Chang[1], Amy Wesolowski[2], Ipsita Sinha[3], Christopher Jacob[4], Amir Hossain[5], Abul Faiz[6], Olivo Miotto[3], Dominic Kwiatkowski[4], Richard Maude[3], Caroline Buckee[1]

[1]Harvard T.H. Chan School of Public Health, Boston, MA, United States, [2]Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States, [3]Mahidol University, Bangkok, Thailand, [4]Wellcome Sanger Institute, Hinxton, United Kingdom, [5]Chittagong Medical College, Chittagong, Bangladesh, [6]Dev Care Foundation, Dhaka, Bangladesh

Regular circulation of individuals to and from malaria endemic areas undermines local control by reintroducing infections and sustaining local transmission. Quantifying the movement of malaria parasites has become a priority for national control programs, but remains methodologically challenging due to the unique evolutionary and epidemiological features of malaria parasite transmission. In particular, high rates of superinfection with multiple strains and a predominance of asymptomatic infections contribute to difficulty in identifying transmission chains and tracking routes of parasite importation. Here, we assessed the utility of genetic data in combination with epidemiological modeling and detailed travel surveys to measure the spread of malaria parasites in Bangladesh. We collected genetic barcodes of 101 SNPs and epidemiological data from 2,137 patients residing in 184 separate unions in Bangladesh. We found that, at this geographic scale, the proportion of parasites with nearly identical barcodes was highly associated with geographic distance, while standard genetic methods, such as average pairwise difference or F_{ST}, were not. We developed a genetic mixing index that quantifies the likelihood of samples from one location having higher-than-expected relatedness to samples from distant locations. We then inferred the direction and intensity of parasite flow between locations as well as estimated the proportion of imported cases using epidemiological models. Our results show distinct regional mixing in the north and south of the malaria-endemic region in Bangladesh, and that the level of parasite mixing is highest in the northwestern region.

1776

UTILIZING *IN SILICO* TOOLS TO PERFORM B CELL EPITOPE PREDICTION IN *PLASMODIUM FALCIPARUM*

Gillian Mbambo, Kara Moser, Mark Travassos, Andrea Berry, Shannon Takala-Harrison, Amed Ouattara, Kirsten Lyke, Joana C. Silva

University of Maryland, Baltimore, MD, United States

In silico epitope prediction is a promising alternative to conventional epitope identification methods, which are normally time consuming and can potentially fail to identify epitopes that are not easily captured using *in vitro* assays. However, the utility of this *in silico* approach depends in the accuracy of the predictions. B cell epitopes can be predicted based on sequence or structure and prediction software use a variety of protein properties to determine the likelihood that a peptide sequence is an epitope. We evaluated four different prediction algorithms that utilize different criteria to predict B cell epitopes for their accuracy in predicting B cell epitopes in the parasite *Plasmodium falciparum*, using as controls known antigen sequences for which we have epitope data. The circumsporozoite protein (CSP) is a well characterized malaria antigen for which epitopes are known and have been experimentally validated. CSP is also the basis of the most advanced malaria vaccine, RTS,S. We also plan to make predictions for other antigenic genes such as AMA1, a leading vaccine candidate that is shown to block parasite red blood cell invasion in *in vitro* assays and VAR2CSA, a candidate vaccine target against placental malaria. We evaluated the following prediction software: ABCPred, SVMTriP, BCEPred and BepiPred, which predict linear epitopes using machine learning and propensity scales. Preliminary data indicates that these software tools predict different epitope sets, which differ in the degree of overlap with experimentally validated epitopes, in addition to predicting new unique epitopes. We will present the sensitivity and specificity of each program and attempt to determine the sequence context that contribute to accuracy.

1777

IDENTIFYING A MINIMAL SET OF SNPS FROM MALARIA PARASITE GENOME DATA THAT CHARACTERIZES THE SPATIO-TEMPORAL ORIGIN OF A SAMPLE

Joshua L. Proctor, Kyle Gustafson, Edward Wenger

Institute for Disease Modeling, Bellevue, WA, United States

Molecular data collected from malaria parasites across a range of transmission settings is beginning to inform operationally relevant analyses and modeling for elimination campaigns. The ongoing poliomyelitis eradication campaign is a modern exemplar to malaria control programs for utilizing genetic data to inform intervention efforts. A virus genome sample is collected from each paralytic case and phylogenetically linked to previous samples to inform outbreak responses or identify circulating vaccine derived polio strains. Despite the success in the polio program with virus genomes, linking malaria *parasite* genomes to transmission characteristics and intervention design encounters serious challenges. Difficulties arise due to the multiplicity of infection, the parasite evolutionary clock, and clonal propagation. Here, we discuss our recent

progress analyzing malaria genomic data for elimination planning/ programs. In this study, we analyze the spatio-temporal similarity of over 3,000 sequenced samples of plasmodium falciparum collected from the major endemic countries by the Malaria Genomic Epidemiology Network. Specifically, we characterize the spatial resolution at which the origin of a sample can be geographically predicted while concurrently identifying the minimal required number of single nucleotide polymorphism (SNPs) for the task. Our results are broadly consistent with previous analyses of these malaria genomes; we highlight connections to known, high-value SNP positions. We have also broadened the scope of previous analyses by adapting a recently developed algorithm from machine-learning to automatically identify a minimal number of SNP positions, perform the origin classification task, and evaluate metrics for parasite genomes. We discuss how this novel framework can contribute to elimination planning by helping identify epidemiologically connected regions and constructing region specific haplotypes.

SUPPRESSION OF B CELL IMMUNE RESPONSES SUBSEQUENT TO LOW DOSES OF CHLOROQUINE AND PYRIMETHAMINE; IMPLICATIONS FOR STUDYING B CELL IMMUNITY IN MALARIA MURINE MODELS

Hayley Joseph[1], Emily Eriksson[1], Louis Schofield[2]

[1]The Walter and Eliza Hall Institute of Medical Research, Melbourne, Australia, [2]James Cook University, Townsville, Australia

Immunomodulation by *Plasmodium sp.* contributes to the pathogenesis of malaria. When studying this phenomenon using mice, researchers may administer the anti-malarial drugs chloroquine and pyrimethamine to prevent early fatalities. It's assumed that low doses have little effect on immune responses so drug treated controls are omitted. We investigated B cell activation to carbohydrate and protein with or without subsequent anti-malarial drug treatment using flow cytometry for phenotyping and ELISPOTs to measure antibody secreting cells. Responses were measured at day 14 and 28 after an immunisation boost. The carbohydrate immunisation included synthetic glycophosphatidylinositol (GPI) conjugated to keyhole limpet haemocyanin (KLH), because GPI is expressed by all *Plasmodium sp*. The model protein nitrophenol (NP) conjugated to KLH was used for protein immunisations since responses are already well characterised. As expected, immunisation in the absence of anti-malarial treatment resulted in significantly higher antigen-specific B cell activation compared to naïve mice. Interestingly, when these mice were administered anti-malarial drugs following immunisation, early B cell responses (day 14) reduced to a level no longer significant. Furthermore, for protein immunised mice, the frequency of memory B cells was significantly lesser when directly comparing drug treatment versus no treatment. By day 28, B cells from protein immunised anti-malarial drug treated mice had recovered from suppression. On the contrary, for the carbohydrate immunisations, most B cell responses were significantly higher than naïve mice exclusive of memory B cells. The latter were significantly higher in carbohydrate immunised mice, but not when these mice were administered anti-malarial drugs. In conclusion, when using the malaria murine model, it is imperative that relevant drug-treated controls are included. This will ensure the exclusion of potential anti-malarial drug effects when measuring parasite immunomodulation.

1779

LOW ANTIBODY TITERS AGAINST MALARIA VACCINE CANDIDATES RH5, RIPR AND CYRPA IN NATURALLY INFECTED PEOPLE IN AN ENDEMIC AREA OF MALI

Alexandra Willcox[1], Kazutoyo Miura[1], Rebecca A. Dabbs[2], Jing Jin[2], David J. Pattinson[2], Mahamadou Diakite[3], Simon J. Draper[2], Carole A. Long[1]

[1]Laboratory of Malaria and Vector Research, National Institute of Allergy and Infectious Diseases/National Institutes of Health, Rockville, MD, United States, [2]Jenner Institute, University of Oxford, Oxford, United Kingdom, [3]University of Sciences, Techniques and Technologies of Bamako, Bamako, Mali

An effective malaria vaccine will likely be one necessary component of a multi-faceted effort to eradicate the disease. The reticulocyte-binding protein homologue 5 (RH5), RH5-interacting protein (Ripr), and cysteine-rich protective antigen (CyRPA) are *P. falciparum* blood-stage vaccine candidates that form a complex involved in merozoite invasion of host erythrocytes. RH5 vaccine development is the most advanced, and an RH5-based vaccine was shown to confer protection in an *Aotus* challenge model. Anti-RH5 antibody titers in malaria-endemic areas are reported to be low; however, immune responses against Ripr and CyRPA in natural infections have not been well-documented. Here we use full-length RH5, Ripr and CyRPA proteins in ELISA to measure antibody titers in sera collected at the peak of the transmission season from 405 individuals of all ages living in a malaria-endemic area of Mali. Most individuals had no or low antibody titers against the three proteins: 45% (183/405), 57% (229/405), and 80% (325/405) of subjects had anti-RH5, -Ripr, and -CyRPA titers under the detectable limit, respectively. Titer increases with age until around age 10, after which there is no significant increase, and males had slightly higher titers against RH5 ($p=0.04$). These patterns are similar to trends in overall malaria infection throughout the year in the test population. Anti-RH5 ($p=0.003$) and anti-Ripr ($p=0.004$) titers were higher in individuals with *P. falciparum* infection at the time of serum collection. Within the subset of positive individuals, antigen-specific antibody titers correlate between the three antigens ($p<0.0001$ for RH5 vs. Ripr and CyRPA vs. Ripr; $p=0.03$ for RH5 vs. CyRPA). Overall, these results show that these three antigens are not highly immunogenic in natural infection and suggest that antibody titers are likely correlated with malaria exposure, which will be confirmed with additional ELISAs. Further experiments will be conducted to test the functional activity of these antibodies using the growth inhibition assay (GIA). Our results will support further development of RH5-, Ripr- and/or CyRPA-based vaccines.

1780

INDUCTION OF IL-10 PRODUCING REGULATORY MACROPHAGES EXPRESSING PDL-1 AND ILT3 BY *PLASMODIUM* SPOROZOITES

Professional antigen presenting cells (APCs) like macrophages (Mϕs) and dendritic cells (DCs) can orchestrate immune responses to pathogens. As such, they are central players in the induction of natural and vaccine-induced immunity to malaria. Blood stage malaria parasites are known to suppress APC activation, but very little is known about the effects of sporozoites (SPZ) on APC phenotype and function. Since the first APCs to encounter malaria parasites are located in the human skin, we set out to investigate the response of human skin APCs to SPZ and SPZ antigens. We generated human monocyte derived DCs and Mϕs and stimulated these with *P. falciparum (Pf)* SPZ or recombinant *Pf* circumsporozoite protein (CSP). Both DCs and Mϕs readily take up recombinant CSP, but do not change their phenotype upon doing so. Whole SPZ are preferentially phagocytised by Mϕs (2-10%) instead of DCs (1%). Mϕ uptake of SPZ is strongly increased (up to 30%) by parasite opsonisation with anti-CSP antibodies. Upon stimulation with SPZ, Mϕs increase activation markers CD80 and CD25, but also show enhanced expression of tolerogenic surface markers Programmed death-ligand 1 (PDL-1) and Immunoglobulin-like transcript (ILT)3. Additionally, SPZ-stimulated Mϕs show decreased migration capacity and produce Interleukin 10, a hallmark for regulatory

responses. To confirm that dermal APCs respond to SPZ similar to monocyte derived APCs, we stimulated cell suspensions obtained from human skin explants with mCherry expressing rodent malaria *P. berghei* or recombinant *Pf* CSP. Similar to monocyte derived APCs, dermal APCs readily took up recombinant CSP as well as whole SPZ. SPZ uptake could be enhanced by parasite opsonisation, confirming the macrophage-like phenotype of these dermal APCs. Phenotyping of these cells is ongoing. In conclusion, we show that SPZ induce a regulatory phenotype in human Mϕs. These findings are a first step in enhancing our understanding of the pitfalls of pre-erythrocytic natural and vaccine-induced immunity.

[1]University of Maryland School of Medicine, Baltimore, MD, United States, [2]Malaria Research and Training Center, University Science, Techniques and Technologies, Bamako, Mali, [3]Division of Infectious Diseases, Department of Medicine, University of California Irvine, Irvine, CA, United States, [4]Centre for Immunity, Infection and Evolution, Institute of Immunology and Infection Research, University of Edinburgh, Edinburgh, United Kingdom, [5]Roche Madison, Madison, WI, United States, [6]Duke Global Health Institute, Duke University, Durham, NC, United States

Subtelomeric variable open reading frame (STEVOR) proteins comprise one of three *Plasmodium falciparum* variant surface antigen (VSA) families involved in malaria pathogenesis and immune evasion. Although individuals in malaria-endemic regions likely acquire natural immunity to clinical disease with the development of antibodies against certain VSAs, there is limited knowledge about antibodies against STEVORs following malaria infection. STEVOR proteins are roughly 300 amino acids in length, consisting of a semi-conserved (SC) region flanked by two variable (V1, V2) domains. We hypothesized that antibodies against STEVORs primarily target epitopes located within the SC region given its relative sequence homology. We aimed to identify STEVOR epitopes associated with malaria exposure using six STEVORs from the 3D7 reference genome expressed as either an entire antigen on a protein microarray or 16-mer peptides with 12 amino acid overlaps on a peptide microarray. We determined serorecognition and seroreactivity for these six STEVORs using Malian sera from children ages 1-6 before and at the peak of a malaria season and adults before a malaria season. Sera from Malian adults (N=18) recognized and had significantly greater reactivity to all six STEVORs compared to sera from Malian children (N=75). For each of the six STEVORs, adult sera (N=10) recognized more peptides in the SC and the V2 regions than pediatric sera (N=10). Adult sera also had increased reactivity to subsets of peptides within the V1, V2, and SC domains. Pediatric sera collected at peak-season (N=10) recognized significantly more peptides in total for each of the six STEVORs than matched pediatric sera collected during pre-season; however, peptide recognition between these two groups did not differ for STEVOR domains individually. Pediatric sera collected at peak-season compared to pre-season did not react more intensely to any group of peptides within a particular STEVOR domain or even spanning each of the six STEVORs. These findings will help elucidate STEVOR epitopes and domains associated with malaria exposure and potentially protective immunity to malaria.

1782

E3 UBIQUITIN LIGASE MARCH1 IS MASTER REGULATOR OF IMMUNE RESPONSES TO MALARIA INFECTION

Jian Wu

National Institute of Allergy and Infectious Diseases/National Institutes of Health, Rockville, MD, United States

A well-tuned immune response is critical for the host to fight against infections. Regulators of molecular signaling pathways play an important role in regulating host immune responses. Previously, we performed a trans-species eQTL analysis of host-malaria interaction and identified many Type-I interferon (IFN-I) related/induced genes, including a gene called Membrane-Associated RING Finger Protein 1 (MARCH1 or RNF171). MARCH1 is an E3 ubiquitin ligase known to ubiquitinate CD86 and MHC class II proteins in immature dendritic cells. Here we showed that the MARCH1 is a master regulator of host immune response during malaria infection. Overexpression of MARCH1 suppresses STING and MAVS mediated IFN-I responses, whereas March1 deficient cells exhibit elevated IFN-I levels. However, March1 KO mice produced significantly lower levels of IFN-I *in vivo* and were better protected than wild type mice after malaria infection, suggesting additional malaria-stimulated signaling pathways. Further analyses revealed that MARCH1 not only regulates STING and/or MAVS activities, but also interacts with many other regulators to fine-tune host immune responses. This study demonstrates new roles for MARCH1 in innate and adaptive immunity during malaria infection.

1783

MALARIA INFECTION-INDUCED SYSTEMIC INFLAMMATION IN PREGNANT WOMEN LIVING WITH HIV RECEIVING CART AND DAILY PROPHYLACTIC TRIMETHOPRIM-SULFAMETHOXAZOLE

Chloe McDonald[1], Andrea Weckman[2], Andrea Conroy[3], Peter Olwoch[4], Paul Natureeba[4], Moses Kamya[4], Diane Havlir[5], Grant Dorsey[5], Kevin Kain[1]

[1]University Health Network, Toronto, ON, Canada, [2]University of Toronto, Toronto, ON, Canada, [3]Indiana University, Indianapolis, IN, United States, [4]Makerere University, Kampala, Uganda, [5]University of California San Francisco, San Francisco, CA, United States

In sub-Saharan Africa the risk of HIV and malaria co-infection poses an important health risk to pregnant women. Women living with HIV (WLHIV) have an increased incidence and density of peripheral and placental malaria infection, and severe clinical complications associated with malaria in pregnancy, including maternal anemia and low birth weight. Here we examined longitudinal changes in inflammatory markers in a cohort of pregnant women in Tororo, Uganda living with HIV who were receiving CART as well as daily prophylactic treatment with trimethoprim-sulfamethoxazole. Plasma samples (n = 1115) from 326 women with singleton pregnancy were processed by ELISA to quantify concentrations of CHI3L1, CRP, IL-18BP, IL-6, sICAM-1, and sTNFR2. Linear mixed effect (LME) modelling was used to examine longitudinal changes in analyte concentrations across gestation. 41% of women had evidence of malaria infection at delivery by PCR, placental histology, placental blood smear or placental rapid diagnostic test. The majority of malaria cases were identified by placental histology (33%). Malaria infection in pregnancy was associated with elevated sTNFR2 ($p < 0.001$), sICAM1 ($p < 0.01$) and IL18BP ($p < 0.001$) across pregnancy. Based on the role of inflammation in preterm delivery we examined longitudinal changes in inflammatory proteins in preterm and term deliveries. Women who delivered preterm had elevated concentrations of sTNFR2 ($P < 0.05$) and elevated levels of IL-6 ($P < 0.05$). When we examined protein concentration in the sample collected prior to delivery, we observed an increased relative risk of preterm in women with plasma concentrations of sICAM-1 ($P < 0.05$) and sTNFR2 ($P < 0.05$) in the highest quartile. Our results suggest that malaria infection in WLHIV, despite daily treatment with trimethoprim-

sulfamethoxazole, can induce a systemic inflammatory response that may increase the risk of preterm birth. These findings highlight the need for additional strategies to protect WLHIV from malaria infection in pregnancy to promote healthy outcomes for mother and child.

T-FOLLICULAR HELPER CELLS IN THE INDUCTION OF FUNCTIONAL ANTIBODIES IN CHILDREN IN HIGH MALARIA TRANSMISSION AREAS

Jo-Anne Chan[1], **Lauren E. de la Parte**[2], Gao Feng[3], Rek John[4], James Beeson[3], Margaret Feeney[5], Bryan Greenhouse[6], Grant Dorsey[6], Moses Kamya[7], Isaac Ssewanyana[4], Prasanna Jagannathan[2], Michelle J. Boyle[1]

[1]Burnet Institute, Melbourne, VIC, Australia, [2]Stanford University, Stanford, CA, United States, [3]Burnet Institute, Melbourne, Australia, [4]Infectious Diseases Research Collaboration, Kampala, Uganda, [5]Department of Pediatrics, University of California San Francisco, San Francisco, CA, United States, [6]Department of Medicine, University of California San Francisco, San Francisco, CA, United States, [7]School of Medicine, Makerere University, Kampala, Uganda

T-follicular helper CD4 T cells (TfH) are the key T cell subset responsible for mediating B cell activation and antibody induction during infection. The induction of different TfH subsets appears to be pathogen-specific. However, in human malaria infection, the specific TfH subsets required for the induction of protective antibodies has not been identified, and the impact of age on TfH subsets activation during *P. falciparum* infection is unknown. Here, we assessed TfH responses children aged 6 months to 10 years residing in settings of high malaria transmission in Uganda via flow-cytometry. Concurrently, the level and function of naturally acquired *P. falciparum* antibodies responses to blood stage parasites were measured. We detected high levels of IgM and cytophillic subclasses, IgG1 and IgG3 in the majority of serum samples tested. We found that these serum antibodies promoted complement deposition on whole merozoites and merozoite antigens, MSP2 and AMA1. Furthermore, serum antibodies had the potential to cross-link Fc-receptors to promote opsonic phagocytosis. The acquisition of functional antibodies increased with host age and was/not associated with protection against clinical malaria. Preliminary results suggest that higher circulating TfH frequencies are associated with a greater number of functional antibody responses to merozoites and merozoite antigens. Associations of TfH with age, prior malaria exposure and antibody induction are currently being assessed and TfH subsets associated with functional antibodies will be reported at the conference. These findings have major implications to further understand the appropriate TfH responses required to increase malaria vaccine efficacy.

1785

INNATE IMMUNE ACTIVATION IN HEALTHY MALARIA-IMMUNE ADULTS FROM WESTERN KENYA

Katherine R. Dobbs[1], Slim Fourati[1], Paula Embury[1], Peter Sumba Odada[2], Bruce A. Rosa[3], Makedonka Mitreva[3], Rafick-Pierre Sekaly[1], James W. Kazura[1], Arlene E. Dent[1]

[1]Case Western Reserve University, Cleveland, OH, United States, [2]Kenya Medical Research Institute, Kisumu, Kenya, [3]Washington University, St. Louis, MO, United States

Frequent exposure to malaria and other infectious diseases endemic in western Kenya may lead to chronic inflammation and altered innate immune homeostasis. We assessed monocyte activation in healthy malaria-immune adults from western Kenya compared to malaria-naïve adults from the United States. All Kenyan adults were Pf PCR negative at time of sample collection. Proportions of monocyte subsets were measured by flow cytometry. Isolated monocytes were cultured 18 hrs with media alone, a TLR2/1 agonist (Pam3CSK4), or a TLR7/8 agonist (CL075); supernatant cytokines were measured with a magnetic bead-based immunoassay. Monocyte gene expression profiles were analyzed with a targeted digital RNA sequencing panel. Monocyte genomic DNA was isolated for DNA methylation analysis using the MethylationEPIC array. We found that Kenyan adults had higher proportions of the inflammatory $CD14^{+}CD16^{++}$ non-classical monocyte subset compared to US adults (10.2 vs. 2.9%, p=0.005). Monocytes from Kenyan adults were hyper-responsive to TLR agonists: production of IL-6 was 4-fold higher with TLR2/1 and TLR7/8 stimulation, and TNF production was 5-fold higher with TLR7/8, in Kenyan vs. US monocytes (p<0.0001). Ex vivo monocyte gene expression profiles showed significant over-expression of inflammatory genes in Kenyan vs. US adults, including *IL1A, IL1B, IL6, TNF, PTGS2, STAT4, NLRP3*, *IFITM1*, and *C1QB*. We found differential DNA methylation patterns clearly separating Kenyan and US groups by principal components analysis; the main drivers of methylation values were sex and geographic location. In addition, gene set enrichment analysis revealed decreased DNA methylation in regions of genes in the Allograft Rejection, Oxidative Phosphorylation, and PI3K/AKT/MTOR pathways in Kenyan vs. US adults. These data are consistent with chronic innate immune activation and inflammation in healthy malaria-immune Kenyan adults compared to malaria-naïve US adults. These differences in immune homeostasis may contribute to differences in vaccine immunogenicity and, more broadly, the long-term health consequences of inflammaging in healthy Kenyan and US adults.

1786

DYSREGULATION OF PRO-AND ANTI-INFLAMMATORY CYTOKINES AND CHEMOKINES AND ANGIOGENIC FACTORS IN INDIVIDUALS IN AREAS OF STABLE AS COMPARED TO UNSTABLE *PLASMODIUM FALCIPARUM* TRANSMISSION

Katrina Co[1], Elizabeth Fernander[1], George Ayodo[2], Lindsey B. Turnbull[1], Eliud O. Onyango[2], Chandy C. John[1]

[1]Ryan White Center for Pediatric Infectious Diseases and Global Health, Department of Pediatrics, Indiana University School of Medicine, Indianapolis, IN, United States, [2]Kenya Medical Research Institute, Center for Global Health Research, Kisumu, Kenya

The effect on malaria transmission on baseline levels of pro- and anti-inflammatory cytokines and chemokines and growth factors in children and adults is not well characterized. We measured the levels of 19 pro- and anti-inflammatory cytokines, chemokines, and growth factors in plasma in children <5 years of age and individuals ≥5 years of age in areas of western Kenya with stable (Ajigo, Siaya County) and unstable (Kipsamoite and Kapsisiywa, Nandi County) transmission. Children in the stable transmission area <5 years (n = 178) had higher levels of IL-1b, IL-12, IL-17A, IFN-γ, MIP-1b, RANTES, IP-10, MCP-1 (MCAF), IL-4, IL-10, and FGF-basic but lower levels of IL-6, IL-8, MIP-1a, IL-1ra, G-CSF, PDGF-bb, and VEGF (all $p < 0.0001$) than children in the unstable transmission area (n = 94). TNF-α levels did not differ between the sites. Findings were similar in *P. falciparum* PCR negative children <5 years (stable, n=144, unstable, n=94). Individuals ≥5 years of age in the stable transmission area (n=96) had higher/lower levels of the same markers compared to those in the unstable transmission area (n=42) as those <5 years with the addition of elevated TNF-α ($p = 0.0007$) in stable transmission, and without differences in MIP-1a. Findings were similar in *P. falciparum* PCR negative individuals ≥5 years (stable, n=79; unstable, n=42). Children and adults in areas of stable malaria transmission, whether actively infected or not, have higher levels of both pro- and anti-inflammatory cytokines than individuals in unstable malaria transmission areas, but lower levels of factors that affect angiogenesis than individuals in unstable transmission. The study findings suggest that stable malaria transmission leads to upregulation of pro- and anti-inflammatory cytokines and downregulation of angiogenic factors even in the absence of active infection. The long-term clinical consequences of this dysregulation of inflammation and angiogenesis require further study.

1787

THE IMPACT OF SEX AND HOST VARIABILITY IN THE OUTCOMES OF IMMUNIZATIONS WITH *PLASMODIUM VIVAX* DUFFY BINDING PROTEIN DBP II IN MICE

Sai Lata De[1], Siriruk Changrob[2], Shulin Xu[1], Francis Ntumngia[1], John H. Adams[1]

[1]Department of Global Health, University of South Florida, Tampa, FL, United States, [2]Department of Clinical Microbiology and Applied Technology, Faculty of Medical Technology, Mahidol University, Bangkok, Thailand

Vaccines seek to induce long-lasting protective immunity to microbial pathogens by focusing immune responses to epitope targets, sensitive to broadly neutralizing immune inhibition. Murine studies with some parasite antigens have produced high-titer, parasite-specific inhibition *in vitro*; however, the clinical outcome of these candidates have not generated a strong anti-parasitic response upon parasite challenge. To date, there is no subunit vaccine clinically available that is capable of eliciting cellular responses or cellular memory and this has been a major limitation in the progress of malaria vaccines. In this pilot study, we evaluated the variation in the immune responses elicited by male and female mice immunized with Duffy-binding protein II (DBPII), a leading pre-clinical vaccine candidate against *Plasmodium vivax* malaria. The goal is replicate induction of high-titer, broadly neutralizing antibodies that occur in 'elite responder' individuals living in endemic countries. Important aspects of our studies are to evaluate the impact of sex and the variation in the HLA class II genes on the development and persistence of the antibody responses to DBPII. Inbred (BALB/c) and outbred (Swiss ND4) mice were immunized with DBPII formulated in CpG and alum, which both produced high antibody titers and a strong Th1 and Th2 response. Phenotypic analysis was performed by flow cytometry using different cell surface markers specific for immune cells. The kinetics of B cell memory responses were characterized using murine markers such as CD73 and CD80. The central and memory T cells were defined by murine markers CD44 and CD62l. The activation of MHC class I and class II were studied. We observed high antibody titers and strong memory B cell responses after four immunizations. These data provide further insight to designing the immunization schedules in ethnicity-specific males and females for DBPII and its related allele variants.

1788

MALARIA CONTROL IN GHANA: PREVALENCE OF PARASITE AND HOST FACTOR

Aminata Lam, Aminata Lo, Aida Gaye, Isaac Akhenaton Manga, Marie Pierre Diouf, Omar Gaye, Babacar Faye

Parasitology & Mycology Service of UCAD, Dakar, Senegal

The transmission of malaria parasites depends on the presence of the sexual stages (gametocytes) of *Plasmodium falciparum* in the blood. The probability of establishing an infection in the mosquito depends on several factors including the densities of male & female gemotcytes as well as their sex ratio. These factors are therefore important determinants of the fitness of *P. falciparum.* The availability of functional antibodies against gametocyte antigens including Pfs48/45 and complement dependent Pfs230 & other sexual stage antigens can neutralize & / or prevent the further development of these sexual stage parasites into infectious sporozoites. We intend to compare the prevalence of gametocytes, transmission blocking & merozoite antibodies against Pfs48/45, Pfs230 & MSP3 in two areas: Obom, with high transmission intensity & Asutsuare, with low transmission intensity. We also try to determine the diversity of factors such as cytokines which also may influence malaria gametocyte development. Blood samples were collected from *P. falciparum* infected & uninfected patients living in two different malaria transmission intensity. Total IgG (and subclasses IgG1 & IgG3) and IgM levels are determined by ELISA. The levels of cytokines in the plasma are estimated by Multiplex. Gametocyte prevalence is measured by microscopy & qRT-PCR. We noted overall that our work confirmed the natural acquisition of antibody against sexual as well as asexual stage parasite antigen. Our results are not sufficient to explain the contribution of cytokine on gametocyte carriage and thus its contribution to malaria transmission. These results confirmed the decrease of malaria showed by a low prevalence of gametocyte in the endemic area.

1789

CONTROLLED HUMAN MALARIA INFECTION INDUCES TRAINED INNATE IMMUNE RESPONSES IN HEALTHY VOLUNTEERS

Jona Walk, Charlotte L. de Bree, Rob J. Arts, Bas A. Blok, Mihai G. Netea, Robert W. Sauerwein

Radboud University Medical Center, Nijmegen, Netherlands

Controlled human malaria infection (CHMI) is an infection of healthy volunteers through bites of laboratory reared and *Plasmodium* infected *Anopheles* mosquitoes. This model has been effectively used to unravel the induction and duration of adaptive immunity and evaluate the protective efficacy of vaccines. However, the induction of innate immunity and a possible lasting effect of *Plasmodium* parasites on innate immune cells (trained innate immunity) has never been explored. In vitro monocyte cytokine responses to stimulation with *E. coli* lipopolysaccaride (LPS), *Candida albicans*, *Staphylococcus aureus*, *Salmonella* and *Mycoplasma tuberculosis* were analysed in five healthy volunteers undergoing a CHMI. During infection, monocyte responses to all pathogens were severely diminished compared to baseline. However, four weeks after infection, cytokine production was consistently higher than at baseline. This is the first evidence indicating that *in vivo* infection with *P. falciparum* leads to trained innate immunity in humans.

1790

ROLE OF THE KUPFFER CELL CD68, A *PLASMODIUM* SPOROZOITE RECEPTOR, IN MODULATION OF EXPERIMENTAL CEREBRAL MALARIA (ECM)

Sung-Jae Cha, Marcelo Jacobs-Lorena

Johns Hopkins University, Baltimore, MD, United States

Role of the Kupffer cell CD68, a *Plasmodium* sporozoite receptor, in modulation of experimental cerebral malaria (ECM). Sung-Jae Cha and Marcelo Jacobs-Lorena *Johns Hopkins Bloomberg School of Public Health, Department of Molecular Microbiology and Immunology and Malaria Research Institute, 615 N. Wolfe St., Baltimore, MD, 21205, USA* ABSTRACT Malaria infection of a vertebrate host starts with liver infection by *Plasmodium* sporozoites. Sporozoites move from the mosquito bite site to the liver via the blood circulation and leave the circulation by traversing Kupffer cells that line the liver blood vessels. Traversal requires interaction between the CD68 Kupffer cell receptor and the sporozoite surface-GAPDH ligand. We previously reported that a strong (~70 %) reduction occurs in the efficiency of sporozoite liver invasion in CD68 knockout (KO) mice compared to wild type controls. More recently, we made the unexpected observation that development of experimental cerebral malaria (ECM) in these CD68 KO mice is strongly inhibited. This inhibition only occurs when the mice are infected with sporozoites, not when infected with blood-stage parasites. Importantly, transfer of plasma from a sporozoite-infected CD68 KO mouse into a wild type mouse induces the ECM-inhibitory phenotype in the recipient mouse suggesting that ECM inhibition is mediated by soluble factors. In support of this hypothesis, we found that the plasma from sporozoite-infected CD68 KO mice has a dramatically different biomarker activation profile compared to wild type (WT) mice. We hypothesize that in the absence of a CD68 receptor, sporozoites traverse Kupffer cells or endothelial cells by breaching them, causing cellular injury and release of protective factors. We identified several candidate cytokines, chemokines, and growth factors that are likely correlated with the ECM-suppression phenotype. This line of investigation may lead to novel approaches for prevention of ECM development and malaria death.

1791

USING MACHINE LEARNING TO IDENTIFY DISTINCT IMMUNE SIGNATURES INDUCED BY NOVEL ADJUVANT FORMULATIONS

Sidhartha Chaudhury[1], Elizabeth H. Duncan[2], Tanmaya Atre[2], Casey K. Storme[2], Stephen Kaba[2], Kevin Beck[3], David E. Lanar[2], **Elke S. Bergmann-Leitner**[2]

[1]BHSAI, Frederick, MD, United States, [2]Walter Reed Army Institute, Silver Spring, MD, United States, [3]Miltenyi Biotech Inc, San Diego, CA, United States

The success of recombinant vaccines often depends on the selection of adjuvants that drive the magnitude, type, and quality of the vaccine-induced immune response. In this study, we combined broad immunoprofiling of antibody, cellular, and cytokine responses with multivariate analysis and machine learning methods to provide quantitative insight into exactly how different adjuvant formulations alter the resulting vaccine-induced immune response. The current study uses a self-assembling nanoparticle (SAPN) presenting the malarial circumsporozoite protein as model vaccine to describe the impact of different three different liposomal adjuvant formulations, alum (ALFA), liposomal adjuvant QS21 (ALFQ), and both (ALFQA), delivered at two different antigen doses. Initial univariate analysis revealed that the adjuvant formulation did not only impact the type of immune response (Th1 vs. Th2), but also the fine specificity of the antibody response. Using a computational approach that integrated a wide range of immune response data, we identified vaccine-induced immune responses and developed a multivariate model that was capable of identifying the vaccine adjuvant condition from the resulting immune response data alone with 92% accuracy ($p = 0.003$). Furthermore, using linear regression modeling, we were able to determine the relative contribution of ALFA and ALFQ components in the combined ALFQA adjuvant formulation. This approach enabled us to define unique immune signatures for the ALFA and ALFQ adjuvant formulations and quantitatively describe how those adjuvant combinations interact with each other in the mixed formulation. Furthermore, we found that by using multivariate analysis and machine learning, we were able to define clear, reliable, immune response characteristics across different adjuvant formulations and antigen doses (six conditions in total), with a relatively small sample size of three animals per vaccine condition - demonstrating the potential of using machine learning methods to integrate data collected from a broad sampling of vaccine and adjuvant formulations.

1792

MODELING THE IMPACT OF DIFFERENT LARVICIDING DEPLOYMENT REGIMENS TO INFORM STRATEGIC PLANNING

Manuela Runge[1], Salum Mapua[2], Fredros Okumu[2], Tom Smith[1], Emilie Pothin[1]

[1]Swiss Tropical and Public Health Institute; University of Basel, Basel, Switzerland, [2]Ifakara Health Institute, Ifakara, United Republic of Tanzania

By targeting outdoor malaria vectors, larviciding may complement insecticide treated nets and indoor residual spraying. Given the possibilities that longer lasting agents or novel deployment strategies might become available, large scale implementation is being reconsidered. However, not much is known about the effects of different deployment regimens on vector abundance and malaria burden. In this modelling study we explored a wide range of deployment variables to define their relative impact in different transmission settings. We used a population-based mathematical model to simulate the impact of larviciding on vector density, entomological inoculation rate and human malaria prevalence during and after the intervention. Deployment variables were: coverage, start and duration of intervention, effectiveness decay (for microbial larvicides or insect growth regulators), frequency, and seasonal targeting. Transmission seasonality was defined using data from Kilombero Valley in Tanzania. We found that larviciding had the largest impact at low transmission intensity, but this was strongly dependent on coverage and timing. At higher transmission intensity, only high coverage during the wet season had substantial effects. At high transmission, frequent deployment during one wet season had more impact on prevalence than covering consecutive wet seasons with fewer deployments. Overall, larviciding during two wet seasons, with a break during the dry season, was more effective in reducing the prevalence than larviciding during wet and dry season in the same year. Continuous larviciding for at least one year achieved a higher and longer lasting impact when starting at the peak of the rainy season than starting at the end of the dry season. Finally, a similar impact could be achieved with different deployment regimens. Hence, the results could support efficient planning of larviciding strategies adapted to local settings. Our modelling framework could help guide National Malaria Control Programs in adopting and coordinating the deployment of larviciding at large scale.

1793

WARMER TEMPERATURES AND SPATIALLY COUPLED TRANSMISSION DYNAMICS IN HIGHLAND MALARIA

Amir S. Siraj[1], Edward B. Baskerville[2], Menno J. Bouma[3], John H. Huber[1], Damtew Yadeta[4], Paul C. Sutton[5], Alex Perkins[1], Mercedes Pascual[2]

[1]University of Notre Dame, Notre Dame, IN, United States, [2]University of Chicago, Chicago, IL, United States, [3]London School of Hygiene & Tropical Medicine, London, United Kingdom, [4]Oromia Regional Health Bureau, Addis Ababa, Ethiopia, [5]University of Denver, Denver, CO, United States

Highland malaria remains a major global problem despite several decades of control efforts. The development and survival of the *Plasmodium* parasite and its mosquito vectors are associated with climatic factors, raising concern over the consequences of global climate change. It has been demonstrated that the inter-annual temperature variability modulates the altitudinal distribution of malaria incidence, expanding the disease into higher elevations during warmer years. While the analysis of retrospective data for such epidemic-prone areas has suggested interactions between regions of contrasting elevation and epidemiology, the resulting transmission dynamics have remained unexplored. To examine the dynamics, including in response to future climate, we identified two main regions: a 'spatial-reservoir' region comprising of localities with relatively stable transmission and cases reported year-round; and an 'expansion' region whose localities are more prone to epidemic outbreaks and report cases only during these events. We then formulated a process-based model, coupling transmission in humans and vectors, and between these two adjacent regions, with key parameters a function of climatic factors. Our results show that a spatial model coupled through the movement of infectious and susceptible humans fits the data best when we account for the different climatic conditions of these two regions. Assuming the seasonality of temperature and rainfall in the two regions remains unchanged, a 1ºC increase in local temperature would result in increases of 18% and 112% in annual cases for the reservoir and expansion regions respectively. These changes would also be accompanied by differential effects on the seasonality of transmission, where the reservoir region becomes more stable with smaller peaks, and the expansion region develops larger peaks. These results should apply more broadly to other highland regions in Africa and South America, both in terms of the increases in number of people at risk of malaria under unmitigated conditions, and the type of interventions that would be most appropriate given the changing seasonal patterns.

1794

MODELING THE ADDED BENEFITS OF SUPPLEMENTAL INTERVENTION TOOLS ON MALARIA TRANSMISSION IN ENDEMIC SETTINGS IN WESTERN KENYA HIGHLAND

Ming-Chieh Lee, Amruta Dixit, Guiyun Yan

University of California Irvine, Irvine, CA, United States

In the past decade, mosquito control interventions such as massive scale-up of insecticide-treated nets (ITN) and indoor residual spraying (IRS), together with the introduction of artemisinin-combination treatments (ACT), have led to substantial reductions in malaria prevalence and incidence in African highlands. However, rising insecticide resistance and increased outdoor transmission have greatly hampered the effectiveness of ITN and IRS, and most highland sites maintain sustained low-level transmission while some others have recently experienced resurgence in malaria rates. Therefore, to determine the efficacy of the supplemental intervention tools that can tackle outdoor transmission and pyrethroid insecticide resistance are urgently needed. Major objective of this research is to evaluate those supplemental intervention tools abilities with special focused on Long-lasting Microbial Larviciding (LLML) in western Kenya Highland. The results show that without supplemental interventions, the impact of LLINs and IRS on malaria transmission and prevalence gradually decline due to increasing insecticide resistance and outdoor transmission. The results indicate that supplementing a LLIN-only intervention with LLML in an area with high insecticide resistance and increased outdoor transmission could reduce the prevalence by 35.2%. Adding LLML to LLIN interventions in areas with little to medium levels of insecticide resistance and increased outdoor transmission could reduce prevalence to 28.5% and 32.5% respectively within 3 years of the initial LLML application. The optimal application time for the LLML intervention is at the start of the dry season when habitats are at their lowest capacity.

1795

ESTIMATING THE HEALTH IMPACT OF A SEASONAL MALARIA CHEMOPREVENTION INTERVENTION IN MALI IN 2017: MODELING DEATHS AVERTED, CASES AVERTED AND DISABILITY ADJUSTED LIFE YEARS (DALYS) AVERTED

Keith Esch[1], Matt Hamilton[2], Eline Korenromp[2], Joseph Lewinski[1], Amy Ratcliffe[1]

[1]Population Services International, Washington, DC, United States, [2]Avenir Health, Glastonbury, CT, United States

Using epidemiological models, Population Services International (PSI) retrospectively estimated the health impact of a seasonal malaria chemoprevention (SMC) intervention, as deaths averted, cases averted and DALYs averted. SMC prevents malaria illness by maintaining a therapeutic antimalarial drug concentration in children ages 3-59 months in areas of highly seasonal malaria transmission through intermittent administration of full courses of antimalarials. Over four months in 2017, PSI and partners procured and distributed over 2.4 million full treatment courses of sulfadoxine-pyrimethamine and amodiaquine (SP-AQ) as SMC to 25 health districts across Mali. Malaria deaths averted, cases averted and DALYs averted were calculated in three steps. Avenir Health's Spectrum-Malaria model was used to estimate the number of under-five (U5) deaths and U5 cases that would be averted in 2018 by increasing SMC coverage levels from 0% to 90% in 2017. The number of U5 deaths averted and U5 cases averted per child receiving a full SMC course were calculated by dividing the output from step one by the number of children that would need to receive SMC to reach 90% coverage. Years of life lost and years of life disabled per malaria death from Global Burden of Disease was overlaid to estimate potential health impact per child receiving SMC. An estimated 0.003 malaria deaths, 0.616 cases and 0.258 DALYs could be averted per child receiving SMC in 2018 in Mali. Across the intervention area, an estimated 7,210 deaths, 1,485,104 cases and 621,892 DALYs could be averted. SMC contributed approximately 25% of PSI's malaria health impact in 2017 in Mali. Long lasting insecticide treated net and artemisinin-based combination therapy distribution comprised the rest. The model can help to set and optimize SMC targets in the context of a national Malaria Strategic Plan. This modeling methodology can be used to proactively estimate the potential health impact of SMC interventions across the Sahel. Spectrum-Malaria can also be applied at the provincial-level and is an increasingly important tool as countries move from control to elimination.

MALARIA PROPHYLAXIS EVALUATION OF LONG-TERM ANTIMALARIAL AGENTS USING PHARMACOKINETICS AND PHARMACODYNAMICS CONSIDERATIONS

Qigui Li, Lisa Xie, Jason Sousa, Jangwoo Lee, Chad Black, Mara Kreishman Deitrick

Walter Reed Army Institute of Research, Silver Spring, MD, United States

Several FDA-approved antimalarial agents, including Malarone (atovaquone-proguanil), doxycycline, and mefloquine, are commonly recommended for preventing malaria in travelers going to malaria-endemic areas using a daily or weekly regimen. Recently, a safety evaluation of mefloquine and doxycycline versus Malarone participants demonstrated that those receiving mefloquine were more likely to discontinue their medication due to adverse effects compared to Malarone and doxycycline users. Although Malarone showed a better safety profile than mefloquine, the absolute risk of malaria during short-term travel appears low with all three agents. Adherence to malaria prophylaxis regimens needs improvement. Evidence from clinical and pharmacokinetics-pharmacodynamics (PK/PD) studies have confirmed that a shortened oral Malarone regimen may convey full protection to the gold-standard dosage regimen. There is another relevant aspect of Malarone PK/PD to consider, namely the very long blood schizonticidal effect which makes this combination attractive for consideration as the first line malaria prophylaxis. So far, there is no perfect option among available antimalarial regimens for long-term travelers and expatriates. Most prophylactic regimens provide about 75% to 95% protection, even if taken correctly, and no prophylactic regimen is 100% effective. To optimize the current regimens, the long-term prophylactic agents with monthly dosage as well as a yearly implantation design are being developed at the Walter Reed Army Institute of Research (WRAIR). In this topical review, we will explore the advantages of our long-term prophylaxis approach in comparison with current drug regimens. We will also examine the evidence behind current indications for the use of Malarone and will summarize the current body of literature surrounding its safety and efficacy. Additionally, this review demonstrates that Malarone may offer a statistically significant prevention benefit with a much longer and safer prophylactic efficacy.

1797

ANTIBODY DENSITY MODEL OF MALARIA TRANSMISSION: PRACTICAL IMPLEMENTATION IN HAITI

Michael C. Collins, Maria Emelianenko, Jenna Krall, Julia Painter, Padmanabhan Seshaiyer, Michael E. von Fricken

George Mason University, Fairfax, VA, United States

In comparison to traditional measures of malaria transmission intensity, serological data is typically less expensive to obtain and has particular utility in areas of low transmission. The commonly used method of analyzing serological data is to estimate seroconversion rate using a catalytic model. This model is limited by the requirement to dichotomize samples into seropositive and seronegative groups, ignoring the differences within groups. While complex mathematical models are frequently used for epidemiological forecasting, they are less often used for data analysis. Methods to estimate malaria transmission intensity via partial differential equation model of malaria antibody density make use of the full continuous nature of the data and typically lead to improved precision in estimates of transmission intensity, but are difficult to

implement. The purpose of this study was to (1) apply such a method to estimate malaria transmission intensity in Haiti and (2) improve the usability of this method. Preliminary results of applying such a method to estimate transmission intensity from samples collected in 2013 from four different sites in the Ouest and Sud-Est departments of Haiti show quantitative differences between the traditional (catalytic model) and novel (partial differential equation model) methods. A total of 831 serum samples were assayed for apical membrane antigen (AMA-1) and merozoite surface protein-1 ($MSP\text{-}1_{19}$). We report and compare results of both traditional and novel analyses of both assays. The usability issues in transitioning a complex model from research to an operational role are significant; overcoming these is a prerequisite to any model gaining wide acceptance. We discuss these usability issues within a general framework for the deployment of complex mathematical models for the analysis of epidemiological data.

1798

DEVELOPING AN INVESTMENT CASE FOR MALARIA ELIMINATION IN KWAZULU-NATAL, LIMPOPO, AND MPUMALANGA, SOUTH AFRICA USING MATHEMATICAL MODELLING

Aparna Kollipara[1], Katie Fox[1], Sheetal Silal[2], Lisa White[3], Joseph Njau[4], Rebecca Graffy[5], Eric Mabunda[6], Gillian Malatje[7], Bheki Qwabe[8], Yogan Pillay[9], Devanand Moonasar[9]

[1]Malaria Elimination Initiative at the University of California, San Francisco Global Health Group, San Francisco, CA, United States, [2]Modelling and Simulation Hub Africa, Department of Statistical Sciences, University of Cape Town, Cape Town, South Africa, [3]Nuffield Department of Medicine, Oxford University, Oxford, United Kingdom, [4]JoDon Consulting Group, LLC, Atlanta, GA, United States, [5]Clinton Health Access Initiative, Inc. (CHAI), Pretoria, South Africa, [6]Limpopo Provincial Department of Health, Polokwane, South Africa, [7]Mpumalanga Provincial Department of Health, Nelspruit, South Africa, [8]KwaZulu-Natal Provincial Department of Health, Pietermaritzburg, South Africa, [9]National Department of Health, Pretoria, South Africa

South Africa (SA) aims to achieve the target of national malaria elimination by 2020. Malaria transmission is restricted to three of the nine provinces in SA: KwaZulu-Natal, Limpopo, and Mpumalanga. From 2012 to 2016 sustained malaria transmission levels were experienced: 1828 local cases and 5249 total cases in 2012; 1100 local cases and 4252 total cases in 2016. In 2017 SA experienced a malaria outbreak in which local and total cases increased to 21882 and 28529 respectively. Transmission has been largely sustained due to population movement across the northeastern border with Mozambique and the northern borders with Zimbabwe, where transmission intensity is significantly higher. SA funds its own malaria programme primarily for IRS and is a member of the Elimination 8 and MOSASWA, regional entities that receive regional funding from the Global Fund (GFATM). However, SA is ineligible to receive a national allocation from the GFATM despite the funding gap to address the additional burden of imported cases. To support malaria elimination efforts in SA, the South African Department of Health and key partners are developing an investment case for elimination. The investment case seeks to determine the micro and macroeconomic costs and benefits of malaria elimination using a mathematical model that projects rates of decline to elimination by 2020. Empirical cost data are incorporated into the model to estimate the cost of elimination and the return on investment of selected interventions against transmission by using estimates of the number of malaria mortality and morbidity cases averted. Numerous scenarios are explored to determine the most cost-effective mix of interventions to achieve elimination. The investment case findings can be used by national and provincial malaria elimination programmes to identify financing gaps, support programme budgeting and strategic planning, and to advocate for sufficient financial resources and political commitment to achieve elimination by 2020 and to maintain elimination status in South Africa. The investment case approach can be adapted for other malaria eliminating countries in Southern Africa.

1799

MODELING THE AGREEMENT AND COST OF INDOOR RESIDUAL SPRAY IMPLEMENTATION STRATEGIES TO CONTROL MALARIA TRANSMISSION

Sadie J. Ryan[1], David A. Larsen[2], Anne C. Martin[3], Derek Pollard[3], Busiku Hamainza[4], Anna Winters[3], Anna Winters[3]

[1]Quantitative Disease Ecology and Conservation (QDEC) Lab, Department of Geography, University of Florida, Gainesville, FL, United States, [2]Syracuse University Department of Public Health, Syracuse, NY, United States, [3]Akros Inc., Lusaka, Zambia, [4]National Malaria Elimination Centre, Lusaka, Zambia

Indoor residual spraying (IRS) is an effective method to control malaria-transmitting *Anopheles* mosquitoes, and often complements insecticide-treated mosquito nets, the predominant malaria vector control intervention. With insufficient funds to cover every household, malaria control programs must balance the malaria risk of a particular human settlement against the financial cost of spraying that settlement. This study creates a framework for modeling the cost of IRS implementation, and applies it to potential targeting strategies in four provinces (Luapula, Muchinga, Eastern, and Northern) in Zambia. We used network models to assess the travel cost between operational bases and target households in settlements identified through remote sensing. We tested the cost of spray strategies assuming 50% of structures were sprayed based on a targeted approach using various risk maps: a) predicted probability of the presence of each of three main anopheline vectors (*An. arabiensis, An. funestus, An. gambiae*), or b) predicted *Plasmodium falciparum* parasite rate in 2-10 year olds (*Pf*PR). The estimated cost of reaching settlements to deliver IRS ranged from $0.01 to $37.89, with 75% of settlements costing $5.80 or less. Costs were no different between targeted and untargeted settlements for *An. arabiensis* and *An. funestus* targeting. Mean spray costs were lowest for settlements when targeting *An. gambiae*, and highest for *Pf*PR, and both of these were significantly cheaper than the mean cost of spraying untargeted settlements with lower values of *Pf*PR and *Anopheles* vector capacity. The *An. funestus* targeting strategy had the highest cost, but the difference was negligible. Differences were observed in the cost of reaching settlements with higher estimates of *Pf*PR and *Anopheles* vector capacity, both in cases of applying blanket IRS and in cases of applying IRS based on risk maps. These findings confirmed the idea that reaching areas with higher malaria burden, which often are more rural and challenging to access, is more expensive than reaching areas with lower malaria burden. More research is needed in how best to apply risk maps for control programs.

1800

ASSESSING THE COURSE OF INFECTION OF DIFFERENT RODENT MALARIA PARASITES IN *GRAMMOMYS SURDASTER* (*GRAMMOMYS DOLICHURUS*)

Solomon Conteh, Jacqueline Kolasny, Yvette L. Robbins, Javonn Musgrove, Brandi Butler, Lynn Lambert, Patrick E. Duffy

National Institutes of Health/ National Institute of Allergy and Infectious Diseases, Rockville, MD, United States

Investigations of malaria are often conducted by examining infections of rodent malaria parasite species in inbred mouse models, which raises the question whether these lab-adapted, artificial hosts accurately recapitulate features of malaria infections in humans. For example, rodent vaccine efficacy results often do not predict protection in humans. African woodland thicket rats (*Grammomys surdaster*) are the natural host for some rodent malaria parasites such as *Plasmodium berghei* and are suspected to be the natural host for *P. vinckei vinckei* parasites. *Thamnomys rutilans* are the natural host for *P. yoelii*, *P. chabaudi chabaudi* and other *P. vinckei*. In published findings, we demonstrated that thicket rats are highly susceptible to various strains of rodent malaria, including *P. berghei, P. yoelii,* and *P. chabaudi chabaudi.* We also confirmed that

thicket rats better reproduce the efficacy of whole organism vaccines reported in human studies compared to laboratory mice. Here, we expand our studies of the thicket rat model by assessing the course of infection with additional malaria species, including various strains of *P. berghei, P. yoelii, P. chabaudi chabaudi*, and *P. vinckei* (*Pv*). We compared the virulence (growth characteristics and lethality) of each parasite species or strain between thicket rats (TR) and laboratory mice (BALB/c and C57Bl6), and we assessed the relative virulence of sporozoite (SPZ)-induced versus blood stage (BS)-induced infection. The relative virulence of parasites in TR versus laboratory mice varied depending on the parasite isolate, and in most but not all cases, early lethality corresponded to accelerated growth. Similarly, the relative virulence of SPZ-induced versus BS-induced infections depended on the parasite isolate and the host. For nearly all parasites, growth characteristics and/or lethality differed between TR and the laboratory mice. These results confirm that the course of rodent parasite infections differ substantially between their natural and artificial rodent hosts, although the nature of the difference is not predictable and requires assessment for each parasite-host combination.

INFERRING THE PARASITE RESERVOIR: UNDERSTANDING THE FORCES THAT SHAPE INDIVIDUAL MALARIA INFECTIONS

Jonathan Russell[1], Andre Lin Ouedraogo[1], Isabel Rodriguez-Barraquer[2], Moses Kamya[3], Joaniter Nankabirwa[3], John Rek[4], Sarah Staedke[5], Isaac Ssewanyana[5], Grant Dorsey[2], David L. Smith[6], Bryan Greenhouse[2], Edward A. Wenger[1], Jaline Gerardin[1]

[1]Institute for Disease Modeling, Bellevue, WA, United States, [2]University of California San Francisco, San Francisco, CA, United States, [3]Makerere University College of Health Sciences, Kampala, Uganda, [4]Infectious Diseases Research Collaboration, Kampala, Uganda, [5]London School of Hygiene & Tropical Medicine, London, United Kingdom, [6]University of Washington, Seattle, WA, United States

Predicting the efficacy of interventions used to interrupt malaria transmission in an endemic population depends on knowing how parasite density is distributed: who is at risk for infection, who is infectious, and what is the appropriate scale for response. Active and passive surveillance measures, including sampling of parasite densities, in malaria-endemic settings provide critical but limited information on the infection and immune status of individuals. Mathematical modeling can bring together disparate data sources into a single explanatory framework that fully describes individual-level infection and immune status. However, an explicit model for the accumulation of acquired immunity to major and minor epitopes arising from multiple strains can be too computationally intensive for large-scale practical applications. Here we combine a statistical model that infers an individual's cumulative exposure and history of infection (malaria age) with a stochastic individual-based model to simulate individual infections across a range of transmission intensities. We use malaria therapy data to draw the shape of an individual infection by deriving transition probabilities between density states for each antigenic wave. Malaria age modulates the transition probabilities and ensuing shape of the malaria infection, which we model through a set of functions parameterized by longitudinal data from the Garki Project in Nigeria and the PRISM study in Uganda. This flexible model framework of infection trajectories and acquisition of immunity can be used to estimate the fraction of the population at any given time with asymptomatic infection and accurately model the intervention impact on populations with dynamic immunity to malaria.

1802

ASSESSING AND PROJECTING THE ROLE OF DISTANCE FROM LOCAL HEALTH FACILITIES ON EARLY CHILDHOOD MALARIA PREVALENCE: A CASE EXAMPLE FROM NORTHERN GHANA

Justin Millar[1], Paul Psychas[1], Benjamin Abuamu[2], Punam Amratia[1], Kwadwo Koram[2], Kok Ben Toh[1], Denis Valle[1]

[1]University of Florida, Gainesville, FL, United States, [2]University of Ghana, Accra, Ghana

Distance to the nearest health facility presents a significant impediment to access to malaria treatment in rural areas throughout sub-Saharan Africa, which can sustain high transmission and prevalence rates. In Ghana, the community-based health planning and services (CHPS) initiative was designed to increase access to quality treatment for malaria and other diseases. In this project, we characterize the role of distance to nearest health facility on early childhood malaria in Bunkpurugu-Yunyoo, a rural district in the Northern region of Ghana. From 2010 to 2013, six biannual surveys collected the malaria status of 10,029 individuals under the age of five years old from 428 communities. Environmental variables, including distance to health facility, were collected from remote-sensed and GIS-derived sources. We constructed a Bayesian regression model which was used to compare distance to health facility to other environmental risk factors, compare the effect of CHPS to traditional health centers, interpolate prevalence across the district, and estimate the optimal location for a new health facility. In both the rainy and dry season surveys, only distance to urban center had a stronger effect than distance to nearest health facility. We did not observe a significant difference between the effects of CHPS compared to traditional health centers, which indicates that the type of facilities does not significantly influence the protective buffer provided by the health facility. The model optimization exercise was used to generate proposed locations for new CHPS compounds. Finally, in order to extend the utilization of our model we created an interactive web application for projecting the impact of proposed locations for a new health facility. We believe that this framework provides a useful tool for supporting data-driven policy decisions to improve access to quality treatment and reduce malaria burden.

1803

THE USE OF REMOTE SENSING FOR ESTIMATING THE RISK OF TRANSMISSION AND PREDICTING CASES OF MALARIA IN ARGENTINA

Ana Cuéllar[1], **María Julia Dantur-Juri**[2], Sylvie Manguin[3], Mirta Santana[4], Camilo Rotella[5], Mario Zaidenberg[6]

[1]Technical University of Denmark, National Veterinary Institute, Frederiksberg, Denmark, [2]Unidad Ejecutora Lillo (CONICET-Fundación Miguel Lillo), San Miguel de Tucumán- Tucumán, Argentina, [3]Institut de Recherche pour le Développement France (IRD), LIPMC, UMR-MD3, Faculté de Pharmacie, Université Montpellier, Montpellier, France, [4]Facultad de Medicina, Universidad Nacional de Tucumán, San Miguel de Tucumán-Tucumán, Argentina, [5]Instituto de Altos Estudios Espaciales Mario Gulich, Centro Espacial Teófilo Tabanera, Córdoba, Argentina, [6]Coordinación Nacional de Control de Vectores, Ministerio de Salud de la Nación, Salta, Argentina

Malaria is a parasitic disease which affects millions of people all over the world. Early warning systems which provide information about spatial and temporal predictions of epidemics might help control and prevent malaria outbreaks. One of the most used tools for the development of such systems are statistic prediction models based on historical reports of cases and indicators of environmental risks. Remote sensing constitutes an essential source of environmental information for the development of these predictive models. The present work is focused on the use of remote sensing for the estimation of the risk of transmission and the prediction of malaria cases in the northwest of Argentina. The study was carried out in San Ramón de la Nueva Orán city, where cases of the disease have been

reported from 1986 to 2005. The existent relationship between reported malaria cases and climatic/environmental variables (Normalized Difference Vegetation Index (NDVI) Normalized Difference Water Index (NDWI) and Land Surface Temperature (LST)) obtained from Landsat 5 and 7 satellite images was analyzed through multilevel Poisson regression analyses. A higher abundance of reported cases of malaria in summer was observed. A model of ARIMA temporal series which included the environmental variables was generated to forecast malaria cases in the year 2000. In turn, the relationship between malaria cases and environmental/climatic factors showed that malaria cases were associated to an increase in LST and in mean temperature and to a decrease in NDVI. This study is expected to be used for the development of future prevention and control actions by the health officials.

1804

ESTIMATING MOBILE FOREST WORKERS' CONTRIBUTION TO MALARIA TRANSMISSION IN SOUTHEAST ASIA: A MATHEMATICAL MODELING APPROACH

Francois Rerolle[1], Jennifer Smith[1], Andrew Lover[1], Bouasy Hongvanthong[2], Sophia Hocini[1], Emily Dantzer[1], Iqbal Elyazar[3], John Marshall[4], Adam Bennett[1]

[1]University of California San Francisco, San Francisco, CA, United States, [2]Center for Malariology, Parasitology and Entomology; Ministry of Health, Vientiane, Lao People's Democratic Republic, [3]Eijkman-Oxford Clinical Research Unit, Jakarta, Indonesia, [4]University of California Berkeley, Berkeley, CA, United States

Recent successes in reducing the malaria burden globally could fail dramatically if resistance to artemisinin-combination therapies continues to expand in Southeast Asia and spreads to high-endemic areas of Africa. Rapid identification and elimination of remaining *Foci* of infection is critical for preventing this. However, these last infections are often the most difficult to identify and eliminate, as they are most prevalent in specific high-risk populations (HRP). Preliminary studies in Champasak Province, Laos, and Aceh Province, Indonesia suggest that HRPs such as forest workers act as mobile reservoirs of infection and transport infections between forest work-sites and other locations. We will use a mathematical modeling approach to assess the relative importance of these HRP groups in sustaining malaria transmission. The Ross-Macdonald model will be extended to include a high-risk human population exposed to a forest-based mosquito population. We plan to inform these models using data from ongoing research sites in Laos and Indonesia where we are collecting data on 1) incidence from passive surveillance records; 2) geo-referenced prevalence data; and 3) gps tracking data of forest workers. Outcomes of interest will include prevalence in high-risk group, proportion of high and low-risk groups in the population and proportion of exposure to forest vs village mosquitoes. The model will enable us to 1) explore the necessity of risk-based population stratification to explain observed malaria infection dynamics in low-endemic settings of Southeast Asia; 2) characterize the HRP groups' key features, in particular in terms of their mobility patterns and interaction with the lower-risk village-based population and; 3) model the effectiveness of HRP targeted interventions on malaria outcomes, evaluating in particular the HRP treatment coverage parameters needed in reactive case detection strategies, respondent driven samplings and adaptive survey designs interventions.

1805

MGDRIVE: A SIMULATION FRAMEWORK FOR GENE DRIVE IN SPATIALLY-EXPLICIT MOSQUITO POPULATIONS AND ITS APPLICATION TO THRESHOLD-DEPENDENT SYSTEMS

Hector M. Sanchez C., Sean L. Wu, Jared B. Bennett, **John Marshall**

University of California Berkeley, Berkeley, CA, United States

Malaria, dengue, Zika, and other mosquito-borne diseases continue to pose a major global health burden through much of the world. The advent of CRISPR/Cas9-based gene editing and its demonstrated ability to streamline the development of gene drive systems has reignited interest in the application of this technology to the control of mosquitoes and the diseases they transmit. The versatility of CRISPR technology has also enabled a wide range of gene drive architectures to be realized, creating a need for their population-level and spatial dynamics to be explored. To this end, we present MGDrivE (Mosquito Gene Drive Explorer): a simulation framework designed to investigate the population dynamics of a variety of gene drive architectures and their spread through spatially-explicit mosquito populations. A key strength of the MGDrivE modeling framework is its modularity: a) a genetic inheritance module accommodates the dynamics of gene drive systems displaying user-defined inheritance patterns, b) a population dynamic module accommodates the life history of a variety of mosquito disease vectors, and c) a landscape module accommodates the distribution of mosquito metapopulations connected by migration in space. To demonstrate the functionality of the software package, we present example MGDrivE simulations for threshold-dependent drive systems: a) reciprocal chromosomal translocations, and b) toxin-antidote-based underdominant systems. These systems are particularly suited to field trials and other local releases as they are expected to: a) spread at their release site following an intentional release, b) only spread to low levels in neighboring populations, and c) be eliminated through dilution with wild-type organisms. Using the MGDrivE framework and metrics from network theory, we describe design criteria for these systems. In closing, we describe other systems to which the MGDrivE framework applies, and future directions for its development.

1806

VALIDATING FUNCTIONAL HEALTH FACILITIES AND CAPACITY FOR IMPROVED DISEASE SURVEILLANCE THROUGH DHIS2: EXPERIENCE FROM KANO AND ZAMFARA STATES, NIGERIA

Usaini Bala[1], Olufemi Ajumobi[1], Amina Abdullahi Umar[1], Adewole Adefisoye[1], Ndadilnasiya Waziri[1], Saheed Gidado[1], Isaac Igbaver[1], Gideon Ugbenyo[1], Edwin Simple[1], Muhammad Gurusu[1], Mathew Binjing[1], Abdulkarim Zubair[1], Yusuf Jega[1], Talatu Tadi[1], Tasiu Sani Habib[1], Fatima Shuayb[1], Mohammed Nura Yahaya[1], Jafar Abubakar[1], Alhassan Da'u[1], Audu B. Mohammed[2], Perpetua Uhomoibhi[2], Basheer Muhammad[3], Munira Ismail[4], Shelby Cash[5], Kwame Asamoa[5]

[1]African Field Epidemiology Network, Abuja, Nigeria, [2]Federal Ministry of Health, Abuja, Nigeria, [3]Kano State Ministry of Health, Kano, Nigeria, [4]Zamfara State Ministry of Health, Gusau, Nigeria, [5]US Centers for Disease Control and Prevention, Atlanta, GA, United States

In 2013, the Nigeria Federal Ministry of Health established a Master Health Facility List (MFL) which has not been updated since. Some health facilities (HF) have ceased functioning and new facilities were built in different areas. These affect calculating indicators in District Health Information System (DHIS) which lacks unique identifiers for HF. We conducted HF service delivery assessment in Malaria Frontline Project areas in Kano and Zamfara states to document HF geo-location, functionality, human resource (HR), DHIS reporting status and reasons for non-reporting. A census of all government HF in each Local Government Area (LGA) was conducted from May to August 2017 using semi-structured questionnaire. The National Primary Health Care Development Agency (NPHCDA)'s classification was used to define functional HF, primary health care (PHCs) facilities and their minimum human resources (HR) requirement. In Kano 20 LGAs, 726 HFs were geo-located, 31 (4.3%) facilities were previously not on MFL, 608 (83.7 %) were PHCs, 118 were secondary or tertiary facilities, 710 (97.8%) facilities were functional and 644/710 (90.7%) reported to DHIS. The 14 LGAs in Zamfara had 739 HFs, 8 (1.1%) were previously not on MFL, 694 (93.9%) were PHCs, 45 were secondary or tertiary facilities, 695 (94.0%) were functional and 656/695 (94.4%) reported to DHIS. Reasons for non-reporting included lack of training and low supportive supervision. Per NPHCDA definition, only 1 PHC in Kano State met the minimum HR requirement for PHC. The results have

improved calculation of indicators by providing accurate numerator and denominator from DHIS. Most HFs were functional but did not meet minimum HR required staff number. Most functional facilities reported to DHIS. MFL should have unique identifiers in DHIS to determine numerator and denominator for rates. Health authorities should address reasons for non-reporting. Regular review of HR strength is essential to provide quality primary health care services. We recommend other States conduct similar assessments to improve DHIS reporting.

1807

PLASMODIUM VIVAX MONO-INFECTION AS MAIN CAUSE OF SEVERE MALARIA IN A CO-ENDEMIC REGION FOR *P. VIVAX* AND *P. FALCIPARUM* IN THE PERUVIAN AMAZON

Diamantina Moreno-Gutierrez[1], Martín Casapía[2], Higinio Quino-Ascurra[2], Juan Celis-Salinas[3], Alejandro Quiroz-Morey[2], Jose Barbosa-Chichipe[4], Alejandro Llanos-Cuentas[5], Philippe Beutels[6], Niko Speybroeck[7], Angel Rosas-Aguirre[8]

Loreto is the department most affected by malaria in Peru. In 2017, it reported 53163 malaria cases (about 90% of total cases in the country), of which 75% and 25% were caused by *P. vivax and P. falciparum*, respectively. Recent reports in South-American co-endemic countries for both species indicated that severe malaria (SM) caused by *P. vivax* is not rare. This observational study describes the characteristics of hospitalized individuals with malaria at the referral hospital in Loreto, Peru. Data were prospectively collected from medical records of hospitalized patients with malaria at the Medicine Unit of the Regional Hospital of Loreto from January 1st to December 30th 2017. Severity was classified based on the criteria published by the World Health Organization (WHO) in 2014. Forty patients with malaria were hospitalized during the study period. The mean age was 39.4±19.5 years (range: 13-89) and the female/male ratio was 1.7/1. SM was identified in 31 patients (31/40, 77.5%), including one woman in the third trimester of pregnancy and one individual with admission diagnosis of ophidism. One third of these patients had confirmed malaria in the past 12 months. *P. vivax* mono-infection (23/31, 74.2%) confirmed by expert microscopy predominated over *P. falciparum* mono-infection (6/31, 19.4%) and mixed infection (2/31, 6.5%) as cause of SM. Among the criteria of severity, prostration was the most common (19/31, 61.3%), followed by shock (12/31, 38.7%), severe anaemia (5/31, 16.1%), jaundice (4/31, 12.9%) and significant bleeding (4/31, 12.9%). About 39% (12/31) of patients with SM had comorbidities, such as diabetes mellitus-2, obesity, chronic kidney disease, immunodeficiency virus infection, hepatitis B, respiratory tract disease, and short bowel syndrome. The pregnant woman with SM had mixed *Plasmodium infection*, and her newborn presented low birth weight (2440 gr.). All SM cases were managed with intravenous artesunate according with WHO treatment guidelines, and evolved favourably without lethal outcomes. *P. vivax* was the main cause of SM in the Amazonian department of Loreto, and it should not be longer considered as "benign" species.

1808

CLOSING THE LOOP: IMPROVING MALARIA TREATMENT CARE AT THE COMMUNITY LEVEL IN MADAGASCAR

Andritiana Tsarafihavy[1], Thomas Razanakatovo[1], Riana Ramanantsoa[1], John Yanulis[1], Aishling Thurow[2], Thomas Hall[3], Laurent Kapesa[4], Jocelyn Razafindrakoto[4]

[1]Management Sciences for Health, Antananarivo, Madagascar, [2]Management Sciences for Health, Medford, MA, United States, [3]Management Sciences for Health, Arlington, VA, United States, [4]President's Malaria Initiative/United States Agency for International Development, Antananarivo, Madagascar

Community health volunteers (CHV) provide integrated management of childhood illnesses services in remote communities in Madagascar, including diagnosing and treating cases of uncomplicated malaria among children less than five years of age (CU5). However, over 50% of CU5 with fever do not seek care. To improve care, the USAID Mikolo Project trained and supervised CHVs in malaria case management in six high-transmission districts and taught them to educate parents about malaria. The project worked alongside CHVs to improve the process of malaria treatment, including educating parents on seeking care from a CHV within 24 hours of the onset of illness; administering a rapid diagnostic test (RDT); treating RDT-confirmed, uncomplicated cases of malaria with artemisinin-based combination therapy (ACT); ensuring that parents have their child adhere to the treatment regimen and follow-up with the CHV; and referring suspected severe malaria cases to the nearest health center. Reports from 1,157 CHVs in 679 Fokontany were included in the analysis. 52,922 febrile children were seen for consultation in 2016; 43% of the cases came within 24 hours of the onset of fever. In 2017, there were 61,114 cases, which is an increase of 15%; likewise 49% of cases of febrile children came within 24 hours of fever onset. In 2016, 99% of the cases were tested with the RDT. This performance decreases slightly to 92% in 2017 due to indivisible RDT kits (a box of 25 units in a hospital kit, which cannot be easily distributed amongst community-level actors). However, in 2017, 34,167 (or 90%) of the cases of malaria were treated with ACT, which is an increase of 12% compared to 2016. Finally, there were 4,253 cases of severe malaria in 2017, which is a reduction of nearly 38% compared to 2016. These results may reflect parents' increased satisfaction with and acceptability of the services provided by CHVs, as they feel more confident in taking their child to the CHV for health care. Parental education on early care seeking, coupled with treatment adherence follow-up by CHVs, can improve the malaria treatment outcome.

MALARIA AND THE MICROBIOME: A SYSTEMATIC REVIEW

Matthew M. Ippolito[1], Joshua E. Denny[2], Charles Langelier[3], Cynthia L. Sears[1], Nathan W. Schmidt[2]

[1]Johns Hopkins University School of Medicine, Baltimore, MD, United States, [2]University of Louisville, Louisville, KY, United States, [3]University of California San Francisco, San Francisco, CA, United States

The microbiome influences malaria parasite fitness and transmission efficiency in mosquitoes, and appears to affect malaria dynamics in mammalian hosts as well. Nascent research examining the interrelationship of malaria and the mammalian host microbiome has yielded interesting insights inviting further study. We conducted a systematic review of the literature examining associations between the microbiome and malaria in mammalian hosts. An electronic search algorithm was adapted to PubMed, MEDLINE, Scopus, Embase, and Web of Science, and reference lists of relevant sources were manually searched. Identified studies (n=4,177) were screened and assessed independently by two authors, and results were compiled in a qualitative synthesis of the evidence. Ten relevant studies were identified. They demonstrate associations between certain intestinal communities and protection against *Plasmodium* infection, and modulation of disease severity. *Plasmodium* infection acutely and reversibly reshapes gut microbial composition in mice. The makeup of

human skin microbial communities may influence mosquito attraction and thus disease transmission. Early research supports a relationship between malaria and the microbiome. The evidence is incomplete, but the observed associations are evocative and signal a promising avenue of inquiry.

HOW DO THE REPORTS TRANSLATE INTO FIELD PERFORMANCE? CROSS-VALIDATION OF DATA FROM ROUTINE REPORTING VS MYSTERY CLIENT VISITS AMONG PRIVATE SECTOR MALARIA PROVIDERS IN MYANMAR

Si Thu Thein, Phone Si Hein, Yan Myo Aung, Manuela Tolmino

Population Services International, Yangon, Myanmar

In 2015, Population Services International (PSI) started the roll out of malaria RDTs among informal private sector providers in Myanmar, to improve the quality and coverage of malaria testing and treatment services in remote areas where formal health care sector coverage is most stretched. These providers were trained to conduct RDTs for all suspected malaria cases and to report the results. Since then, PSI received hundreds of thousands of RDT reports from these providers, yet it was largely unknown whether the providers were testing all suspected fever cases nor how the reports related to actual field performance. Up to October 2017, PSI trained 8,673 providers across 5,331 villages in 15 regions of Myanmar. In November 2017, PSI conducted mystery client (MC) visits to a randomly selected sample of those providers. A local person, "MC", was trained to approach the provider with symptoms suggestive of malaria fever. PSI staff pretended to be a friend of MC and observed provider-client interaction. MCs visited 457 providers across 422 villages within 34 days. The results from the visits were compared against data from routine reports, and possible relationships were explored. From routine data, those 8,673 providers conducted 482,197 RDTs, and detected 6142 malaria cases (1.27% positivity) in 2017. Yet, the performance was not uniform: 1,899 (21.9%) did not report at all, and top-performing 36% among 6,774 reporting providers contributed to 80% of all RDT tests, and just 20% detected all malaria positive cases. Among 457 MC visits, only 79 (17.2%) got tested with RDT. The likelihood of performing RDT was found to be related to routine reporting. Those who reported any RDT testing were 3 times more likely to perform RDT on MC, compared to those who reported none (20.3% vs 6.2%). And those whose RDTs produced zero positives in routine reports were half as likely to perform RDT, compared to those who had detected any positives (15.2% vs. 29.4%). This comparison between routine data and MC visits showed that providers may not test all suspected fever cases, and furthermore, the lack of seeing any malaria positive cases over time could affect their field practice.

1811

IMPACT OF CODON USAGE ON SEQUENCE VARIANT COMPOSITIONS OF *PLASMODIUM FALCIPARUM* CELTOS

Neeraja Punde[1], Patricia Legler[2], Dagmar Leary[2], Jennifer Kooken[1], Evelina Angov[1]

[1]Walter Reed Army Institute of Research, Silver Spring, MD, United States, [2]Naval Research Laboratories, Washington, DC, United States

Numerous proteins are difficult to express in heterologous expression systems. Codon usage frequency is a factor that has been shown to influence final protein structure and function. The frequency with which codons are used imparts vital information on the formation of secondary and tertiary protein structure. Inconsistencies in codon usage can lead to poor levels of overall expression, expression of non-functional, insoluble or truncated proteins. Generally, protein translation and folding in *E.coli* occurs co-translationally. The approach of codon harmonization replaces native codons aligning them with the expression host usage frequency while also identifying putative inter-domain segments to allow for slowing down of translation rates. To address challenges of heterologous expression of *Plasmodium falciparum* target-genes in *E. coli*, a "codon harmonization" approach was applied to the malaria antigen CelTOS (Cell traversal protein for ookinetes and sporozoites). CelTOS plays an important role in traversal of cells in the mosquito and vertebrate hosts and is highly conserved in *Plasmodium* species, suggesting a conserved functional role and making it a desirable candidate for a malaria vaccine. Direct comparison of a codon harmonized-protein and a wild type codon usage-protein at the level of protein expression, solubility, yield, stability, and immunoreactivity against CelTOS-specific mAbs did not show significant differences between the expressed products. Though the difference in expression and yield of the codon-harmonized and native proteins was negligible, we found the proteins to be different in their molecular masses and secondary structure. LC MS/MS detection of low frequency misincorporations in polypeptides against a background of wild-type molecules revealed low level of variant amino acid misincorporation, and a single likely misincorporation event between the two proteins, reflecting a potential error in translation. The implication of amino acid misincorporation on product homogeneity and as a product quality attribute must be considered during preclinical investigations and process development.

HEALTH WORKER'S POST-TRAINING PRACTICES FOR CASE MANAGEMENT OF SEVERE MALARIA IN SOUTHERN NIGERIA

Olatunde M. Adesoro[1], Joaniter Nankabirwa[2], Constance Constance Shumba[2], John Kpamor[1], Olusola Oresanya[1], Madeleine Madeleine Marasciulo-Rice[3], Prudence Hamade[3], Alexis Kamdjou[4], Kolawole Maxwell[1], James Tibenderana[3], Ebenezer Sheshi Baba[2], Helen Counihan[3]

[1]Malaria Consortium, Abuja, Nigeria, [2]Malaria Consortium, Kampala, Uganda, [3]Malaria Consortium, London, United Kingdom, [4]Medicines for Malaria Ventures, Yaunde, Cameroon

Patients with severe malaria require prompt and appropriate treatment to prevent death. Training of health workers on severe malaria case management, provision of commodities for definitive management and ongoing supportive supervision were provided for hospitals in three states in Nigeria. This study was a cross-sectional assessment of severe malaria case management practices of 677 health workers and 562 anonymized records of severe malaria patients in 75 hospitals in the three states using WHO's service availability and readiness assessment (SARA) tools. Data analysis was done using SPSS software. Nurses/midwives (50.4%), doctors (13.1%), community health workers (10%) and pharmacists and laboratory scientists were interviewed. Most hospitals (96.6%) profiled had either rapid diagnostic test kits or microscopy for malaria diagnosis, stocks of injectable artesunate (Inj AS) (89.3%) and artemisinin-based combination therapy (82.7%) during the assessment. Case records of severe malaria patients indicated that diagnosis of severe malaria was documented in 363 (64.6%) out of which parasite-based microscopy was 231 (41.1%). Most of the patients (525, 93.4%) were reported to have received Inj AS for severe malaria within 24 hours of admission. Twenty percent of the patients with negative blood smear were still prescribed an antimalarial. Biological diagnosis of severe malaria was significantly associated with having a functional laboratory (p=0.008), Inj As availability (0.025) and availability of malaria treatment policy chart (p=0.005). Availability of policy chart also significantly influenced appropriateness of antimalarial prescription practices and promptness of antimalarial treatment (p=0.003, and 0.007) with Inj AS. Though availability of Inj AS and diagnostic services were high with prompt treatment of severe malaria cases, there was inadequate microscopy to monitor patient progress. Provision of functional microscopy, continuous supply of injectable artesunate and availability of malaria treatment charts will help to ensure appropriateness manage.

1813

HEMATOLOGICAL DETERMINANTS FOR A G6PD DEFICIENCY AND DRUG-RELATED HEMOLYTIC RISK REGRESSION-BASED MODEL

Michael Kalnoky[1], Emily Emily Gerth-Guyette[1], Cindy Chu[2], Germana Bancone[2], Maria Kahn[1], Gwen Ambler[1], Francois Nosten[2], Gonzalo Domingo[1]

[1]PATH, Seattle, WA, United States, [2]Shoklo Malaria Research Unit, Mae Sot, Thailand

Radical cure for *Plasmodium vivax* with 8-aminoquinoline drugs, such as primaquine, can clear *P. vivax* parasites by killing malaria hypnozoites. However, 8-aminoquinoline drugs can cause severe hemolysis in patients with reduced activity of the glucose-6-phosphate dehydrogenase (G6PD) enzyme. The X-linked G6PD gene mutations resulting in reduced G6PD activity levels are prevalent in malaria-endemic regions, reaching more than 15% prevalence in some Southeast Asian populations. The severity of hemolysis is dependent on the level of G6PD activity, the G6PD allele variant, drug dosing, patient status, and disease factors. The 2D6 isoform of the cytochrome cyp450 (CYP2D6) is the key metabolizer of primaquine and may be associated with both poor response to primaquine treatment and the hemolytic toxicity of the drug. This uncertain risk among those with reduced G6PD activity levels, particularly intermediate levels, represents a major barrier to wide-scale use of radical cure. Using data generated in a clinical trial conducted in Thailand, we aim to develop a regression-based model that will quantify the associated hemolytic risk in females heterozygous for G6PD deficiency upon exposure to 8-aminoquinoline drugs. We will present the proof of concept of a risk model that could be used to predict the severity of hemolysis based on the most significant of the following determinants: age, gender, complete blood count data, G6PD activity levels, distribution of G6PD intracellular activity measured using flow cytometry, primaquine dosage levels, and CYP2D6 phenotype. A model for hemolytic risk based on detailed profiling of intracellular red blood cell G6PD activity levels, combined with novel quantitative point-of-care G6PD diagnostic tests, has the potential to improve clinical treatment guidelines for the radical cure of *P. vivax* using primaquine within the context of G6PD deficiency and other physiological factors.

1814

IDENTIFICATION OF IMMUNE-PROTECTIVE ANTIBODIES AGAINST *PLASMODIUM FALCIPARUM*

Jennifer M. Kooken[1], Sidharta Chaudhury[2], Alexandra Urman[1]

[1]Walter Reed Army Institute of Research, Silver Spring, MD, United States, [2]BHSAI, Fort Detrick, MD, United States

For many of the world's military forces, malaria continues to be a major complicating factor in conflict zones around the world. It drastically, and dangerously reduces troop readiness during times of warfare, and frequently compromising mission readiness in malaria endemic regions. Antibodies against sporozoites are the first line of defense against malaria infection but despite decades of research it is unclear what the fine specificities and/or functional activities of these antibodies are. Currently it is understood that not all immune antibodies specific for sporozoite-expressed antigens are able to block the infection of hepatocytes, in fact only a small subset seem to slow down or block invasion. The identification of invasion slowing or stopping factors would prove invaluable for malaria drug and vaccine development. In working towards this goal proteomic methods were developed to establish the fingerprint of protective antibodies and identify key targets of the humoral immune response utilizing mass spectrometry. With further interrogation of the proteome through bioinformatics we are able to establish profiles of antibodies in the protective and un-protective sera from the IMRAS sera (irradiated sporozoite, NF54, Phase 1 CHMI trial). Further testing allowed for the isolation of schizonts in HC04 human liver cells exposed to pooled protective/un-protective IMRAS sera which were processed and analyzed for infectivity rates. Tables will exhibit pathways defined by the KEGG database, and the PathNet algorithm that is used to identify which protein pathways show statistical enrichment between the infected and non-infected conditions. Compilation of this information allows for bioinformatics analysis finding unique and pertinent proteins (including antibodies and antigens) of interest. With this information drug and vaccine development may become targeted to select candidates that will cure or confer the highest level of protection allowing the warfighter to focus on the mission.

TRANSFORMING THE MARKET FOR QUALITY-ASSURED ACT (QAACT) IN KINSHASA: AVAILABILITY, PRICE AND MARKET SHARE RESULTS FROM A REPRESENTATIVE OUTLET SURVEY IN SUPPORT OF LARGE-SCALE MARKET DEVELOPMENT ACTIVITIES

Stephen Poyer[1], Godefroid Mpanya[2], Willy Onema[2], Paul Bouanchaud[1], Bram Piot[1], Christina Lussiana[3], Joseph Lewinski[1], Marcel Lama[4], Niara Rakotonirina[4], Eric Mukomena Sompwe[5]

[1]Population Services International, Washington, DC, United States, [2]Association de Santé Familiale, Kinshasa, Democratic Republic of the Congo, [3]Population Services International, Nairobi, Kenya, [4]Population Services International, Kinshasa, Democratic Republic of the Congo, [5]National Malaria Control Program, Kinshasa, Democratic Republic of the Congo

The government of the DRC has set 2020 targets of 80% suspected malaria cases tested and 100% confirmed cases appropriately treated, in line with WHO recommendations. The private health sector in Kinshasa is a critical partner in delivering quality malaria care to achieve these targets as it serves 70% of childhood fevers and has 86% antimalarial market share in the city. However, in 2015 QAACT availability was only 19% in drug shops, the most popular antimalarial source. The median private sector adult-equivalent (AE) QAACT course cost $5.04 and QAACT market share was just 2.2%. Beginning in December 2015 PSI, in partnership with the NMCP, negotiated QAACT price reductions with manufacturers, introduced co-payments for importers, conducted large-scale promotion of a Green Leaf quality logo, and supported medical detailing. Additional supporting interventions included the provision of free RDTs to qualified pharmacists and MOH-led supervision. Between Feb 2016 and Feb 2017 manufacturers sold 1.4 million QAACTs to local importers. A city-wide representative outlet survey in Feb 2017 assessed the availability, affordability and market share of QAACTs. 841 private and public outlets were screened for availability of malaria testing and treatment, 831 outlets were interviewed, and 4,929 antimalarial products audited. Standard ACTwatch sampling, fieldwork and analysis methods were used. Availability of QAACT in 2017 increased to 39.2% in private facilities, 58.8% in drug shops and was 93.8% among registered pharmacies. Median retail price for AE QAACT was $1.80 and private sector QAACT market share increased to 14.4%, gaining share from non-artemisinin therapies. These data suggest that subsidized QAACT have been embraced by private providers. After 1 year, this intervention has met the AMFm benchmarks for success for availability and market share, and greatly reduced the price differential between QAACTs and common non-artemisinin therapies. As the co-payment is reduced, ongoing M&E activities will provide valuable lessons on how to maintain private sector market improvements while reducing the reliance on external subsidies.

1816

EXPERIENCES AND PERCEPTIONS OF CARE SEEKING FOR FEBRILE ILLNESS AMONG CAREGIVERS AND PROVIDERS IN EIGHT DISTRICTS OF MADAGASCAR

Andrianandraina Ralaivaomisa[1], Eliane Razafimandimby[1], Jean Pierre Rakotovao[1], Lalanirina H. Ravony[1], Sedera A. Mioramalala[2], Rachel Favero[3], Katherine Wolf[4], Patricia Gomez[3], Jocelyn Razafindrakoto[5], Laurent Kapesa[5]

[1]Maternal and Child Health Survival Program/Jhpiego, Antananarivo, Madagascar, [2]Madagascar Ministry of Health, National Malaria Control Program, Antananarivo, Madagascar, [3]Maternal and Child Health Survival Program/Jhpiego, Baltimore, MD, United States, [4]Maternal and Child Health Survival Program/Jhpiego, Washington, DC, United States, [5]US President's Malaria Initiative, United States Agency for International Development, Antananarivo, Madagascar

Delayed care seeking for febrile illness in Madagascar may contribute to poor outcomes for diseases including malaria, particularly among children and pregnant women. We conducted an assessment with caregivers of children, pregnant women, and clinicians to identify gaps, attitudes and practices that hinder timely care seeking and adherence to national malaria treatment guidelines.In November 2017, we conducted in-depth interviews with 32 pregnant women and 16 caregivers of children < age15 years in eight malaria transmission zones to elicit care seeking behavior information. We conducted 16 focus group discussions (FGD) of approximately 128 participants among this demographic. Thirty-two private and public health care providers were interviewed and completed knowledge tests to describe barriers to and facilitators of health provider adherence to treatment guidelines. Availability of commodities at facilities was tracked. We used descriptive in-depth analyses of recurring themes and quantitative scoring of provider knowledge. Pregnant women and caregivers of children cited poor quality of services, lack of malaria rapid diagnostic tests (RDT) and medications, unwelcoming attitudes of providers, cost, and distance from health centers as reasons for delayed care seeking. Additional influencing behaviors and conditions reported by providers as reasons for delayed care seeking included self-medication, use of traditional healers, fear of hospitalization and not perceiving fever as a severe condition. All providers reported consistently testing febrile patients with RDTs before treatment or transfer, which was confirmed through knowledge tests. While the majority of providers (90%) correctly answered most (80% or more) of the knowledge questions, gaps in knowledge were still apparent. Stockouts of key malaria diagnostic and treatment products was recorded in several facilities. Improving stock management, providing very low-cost care, training clinicians to create a welcoming environment, and raising awareness of the importance of evaluating fevers could improve timely care seeking.

1817

MALARIA AND KAPOSI SARCOMA HERPES VIRUS (KSHV) SEROPREVALENCE IN A COHORT OF CHILDREN IN WESTERN KENYA

Katherine R. Sabourin

University of Colorado, Aurora, CO, United States

Malaria may be an important factor in the transmission of Kaposi sarcoma herpesvirus (KSHV), the etiological agent of Kaposi sarcoma. Both malaria and KSHV are endemic to Sub-Saharan Africa and cause substantial public health burden. We tested samples from a cohort of Kenyan infants, followed through age three, to explore whether children with *Plasmodium* infection compared to no infection are more likely to become KSHV seropositive. Blood plasma from 167 Kenyan children were tested for KSHV and *Plasmodium* sero-response over a three year period. Children were *Plasmodium* seropositive if antibodies to MSP-1 proteins from any of three *Plasmodium* strains (kd42, kda42, and fup) were detected using a bead-based multiplex Luminex assay (Plos Pathogen, 2014 10(3) e1004046). Seropositivity for KSHV was determined by presence of antibodies to either (1) ORF73 or K8.1 or (2) ORF73, ORF61, ORF38, ORF65, ORF59, K8.1, K8.1b, or K5; as detected by Luminex. To determine if *Plasmodium* infection in children led to earlier KSHV seroconversion, we utilized a cox proportional hazards regression model including *Plasmodium* seropositivity as a time varying covariate and KSHV status at 12, 18, 24, 30 and 36 months as outcome. By age three, 157(94%) children were *Plasmodium* seropositive at least once. When measured by K8.1 and ORF73 only, 16(10%) children were KSHV seropositive by age three; compared to 52(31%) when using a broader array of KSHV proteins. We saw a significant increase in the hazard of being KSHV seropositive among children with *Plasmodium* infection versus not, when KSHV was measured using antibodies to eight KSHV proteins (HR=2.3, 95%CI: 1.1-4.9); but no significant difference when measured by K8.1 and ORF73 only (HR=1.7, 95%CI: 0.5-6.1). In conclusion, our study shows that most children will have a *Plasmodium* infection in Kenya by age three, confirming the importance of malaria in the region. In addition, children with a *Plasmodium* infection have a greater risk for infection with KSHV at an earlier age. Malaria may have a potential role in enhancing KSHV transmission, which requires further exploration.

1818

IMPROVING ADHERENCE TO NATIONAL MALARIA TREATMENT GUIDELINES BY VILLAGE MALARIA WORKERS IN SELECTED TOWNSHIPS THROUGH A LOW-DOSE, HIGH-FREQUENCY TRAINING APPROACH

Ni Ni Aye[1], May Aung Lin[2], Saw Lwin[2], Khin Than Win[2], Kyan Khaing[3], Nu Nu Khin[4], Kyaw Myint Tun[2]

[1]Jhpiego, PMI Defeat Malaria Project, Yangon, Myanmar, [2]University Research Co., PMI Defeat Malaria Project, Yangon, Myanmar, [3]Myanmar Nurses and Midwives Association, Yangon, Myanmar, [4]US President's Malaria Initiative, United States Agency for International Development, Yangon, Myanmar

Myanmar, until recently with the highest malaria burden among Greater Mekong Sub-region countries, has seen decreasing morbidity and mortality through scaling up of vector control and case management interventions. The PMI-funded Defeat Malaria project aims to reduce malaria burden and contribute to the national goal of malaria elimination. One of the key strategies is to provide quality diagnosis and early treatment through a network of community-based village malaria workers (VMW) covering 1.5 million people in 33 targeted Townships. This review assessed capacity development of VMWs to adhere to National Malaria Treatment Guidelines (NTGs) through a competency-based low-dose, high frequency (LDHF) training approach. Review of progress through records and reports was conducted before and after LDHF sessions. The approach was used for 87 VMWs from Gwa (Rakhine State) and Palaw (Tanintharyi Region) Townships by 36 township-level general trainers previously trained by 11 State/Region level master mentors. VMWs received on-site trainings on NTGs (in three "doses") in June, July and August, 2017. Post-training follow-up was conducted by clinical audit during supervision visits, routine data quality assessment and verification of monthly reports. Monthly clinical audits revealed decreasing need for verification as most VMWs were using job aids properly and responded correctly to case scenarios during supervision. These results were consistent with beneficiary interviews during on-site data verification. Improvement in adherence to NTGs was assessed as percent of uncomplicated malaria cases that received correct antimalarial treatment. Findings show adherence to NTGs increased from 72% to 100% in Gwa and remained high but unchanged (from 91% to 92%) in Palaw before and after the three-month training period. The LDHF approach was appropriate for capacity building of VMWs on protocol adherence in Rakhine State, but in some circumstances as in Palaw, VMWs will require materials in local languages with culturally appropriate illustrations. These will be formulated and assessed in future reviews.

1819

IMPROVING MALARIA CASE MANAGEMENT (MCM) INCLUDING MALARIA IN PREGNANCY (MIP) THROUGH NATIONAL ROLL-OUT OF MALARIA SERVICE AND DATA QUALITY IMPROVEMENT (MSDQI): A CASE STUDY FROM TANZANIA

Jasmine Chadewa[1], Chonge Kitojo[2], Goodluck Tesha[3], Naomi Kaspar[2], Lusekelo Njoge[1], Zahra Mkomwa[3], Dunstan Bishanga[1], George Greer[2], Abdallah Lusasi[3], Sigsbert Mkude[4]

[1]Jhpiego, U.S. Agency for International Development Boresha Afya Project, Dar es Salaam, United Republic of Tanzania, [2]US President's Malaria Initiative, United States Agency for International Development, Dar es Salaam, United Republic of Tanzania, [3]PATH, U.S. Agency for International Development Boresha Afya Project, Dar es Salaam, United Republic of Tanzania, [4]National Malaria Control Program, Tanzania Ministry of Health, Dar es Salaam, United Republic of Tanzania

As a high malaria burden country facing an increased demand of health services, quality of care remains a major concern for the Ministry of Health (MoHCDGEC) in Tanzania. In response, the MoHCDGEC and partners developed the Malaria Service and Data Quality Improvement (MSDQI) checklist for guiding supportive supervision teams to evaluate the quality of malaria case management (MCM) and malaria in pregnancy (MIP) services at facility level. The USAID Boresha Afya Project, in collaboration with National Ministry Trainers and Region and Council Health Management Teams, supported cascading of MSDQI mentorship to other providers across 1817 facilities in 7 regions, to encourage the monitoring of quality of MCM and MIP services. A standardized health facility MSDQI package was used to observe providers' diagnosis, treatment and antenatal care (ANC) practices. Facilities were selected as part of supportive supervision, with priority given to low performers identified from DHIS2 data. Modules covered included OPD & ANC services, Microscopy, severe malaria, and data quality assessment. Facility performance of each step was scored, summarized within indicator category, and assigned a percentage performance score. Overall providers did well testing febrile patients for malaria (81%), providing correct diagnosis (92%) and provision of correct treatment (86%), yet a large number of facilities did not meet the minimum performance standard of 75% at the OPD. For OPD service provision, the overall score was 71%, with history taking (61%), physical examination (50%), and patient counselling (51%) as the lowest preforming areas. To address quality of care and improve services, Boresha Afya plans to disseminate malaria and ANC guidelines, job aids and SOPs, and continue with supportive supervision and mentorship through the MSDQI tool to build capacity of providers in microscopy, improved diagnostics, and estimation of gestational age. Effective implementation of MSDQI requires systematic preparation of the supportive supervision team, including orientation of the team to roles, competency-based training, resource allocation and use of tablets.

1820

USING THE COLLABORATIVE QUALITY IMPROVEMENT APPROACH TO INCREASE ADHERENCE TO THE TEST, TREAT AND TRACK MALARIA CASE MANAGEMENT FRAMEWORK: EXPERIENCE FROM 10 HEALTH FACILITIES IN UGANDA

Thomson Ngabirano[1], Espilidon Tumukurate[1], Innocent Atukunda[2], Emily Katarikawe[2], Jimmy Opigo[3], Martin Muhire[4], Emily Goodwin[5], Sam Gudoi[5], Kassahun Belay[6], Peter Thomas[7], James Tibenderana[8]

[1]Jhpiego, U.S. Agency for International Development Malaria Action Program for Districts (MAPD) Project, Kampala, Uganda, [2]Jhpiego, Kampala, Uganda, [3]National Malaria Control Program, Uganda Ministry of Health, Kampala, Uganda, [4]University Research Co., U.S. Agency for International Development ASSIT Project, Kampala, Uganda, [5]Malaria Consortium, U.S. Agency for International Development Malaria Action Program for Districts (MAPD) Project, Kampala, Uganda, [6]US President's Malaria Initiative, United States Agency for International Development, Kampala, Uganda, [7]US President's Malaria Initiative, US Centers for Disease Control and Prevention, Kampala, Uganda, [8]Malaria Consortium, Kampala, Uganda

Malaria is the leading cause of morbidity and mortality in Uganda, contributing 30-50% of outpatient visits and half of inpatient pediatric deaths. The President's Malaria Initiative (PMI), through USAID's Malaria Action Program for Districts (MAPD) project, is supporting the Ministry of Health's National Malaria Control Program to improve malaria services in 47 districts through building the capacity and quality service delivery at health facility and community levels. Data reliability at health facilities is critical to providing evidence-based interventions, tracking epidemiological trends and stratification. Through collaborative quality improvement (CQI), MAPD supported improving the quality of malaria service delivery records at selected health facilities. The focus of the data review was to track and improve the malaria test results and compliance with treatment guidelines and the test, treat and track framework. The CQI approach was introduced in November 2017 starting with ten health facilities in the project regions selected for the CQI pilot. Each health facility was coached to improve its ability to review malaria data, identify gaps and develop solutions. Facility improvement teams were formed and each member assigned a role in improving malaria services data management. The improvement process was tracked by the health facility teams through a national quality improvement tool. From November 2017 to February 2018 completeness of malaria patient information in the outpatient register increased from 0 to 86%, concordance of malaria diagnostic information in the laboratory registers and the outpatient register improved from 47% to 100%, patients diagnosed as positive who were treated for malaria increased from 91% to 99%, patients with a negative malaria test treated decreased from 9% to 1%, and pregnant women receiving 3 or more doses of IPTp-SP increased from 43% to 53%. Data is tracked on a monthly basis using documentation journals. The CQI approach has the potential of improving adherence to the national malaria policy of test, treat and track if implemented to scale.

MALARIA DEATH AUDITS: A TOOL TO HELP IMPROVE SEVERE MALARIA CASE MANAGEMENT AND POTENTIALLY PREVENT MALARIA-RELATED DEATHS IN ZIMBABWE

Anthony Chisada[1], Paul Matsvimbo[2], Munekayi Padingani[2], Tsitsi Siwela[2]

[1]Jhpiego, ZAPIM Project, Harare, Zimbabwe, [2]Zimbabwe Ministry of Health and Child Welfare, Harare, Zimbabwe

Nearly 50% of the Zimbabwean population is at risk for malaria. Total numbers of malaria related deaths have remained almost constant over the past 5 years. The National Malaria Control Program's National Malaria Strategic Plan aims to reduce malaria-related deaths by 90% from 2015 levels (462 deaths) by 2020. To improve severe malaria care and reduce mortality, NMCP documents and investigates all malaria deaths to ascertain the cause of the death and understand if and how it was avoidable. Malaria death audit meetings are held quarterly with health facility staff using a standard death investigation form and case management notes, and form a learning platform to look at qualitative and quantitative data related to the deaths. The audits also examine the quality of care offered as per treatment guidelines, and seek to identify ways to prevent future malaria deaths based on omissions and errors in presented cases. This review examines the findings from death audit meetings facilitated by the PMI-funded Zimbabwe Assistance Program in Malaria project in the Zimbabwean provinces of Mashonaland Central, Mashonaland East and Matabeleland North. Six death audit meetings were conducted over an 18-month period, resulting in a total of 80 deaths audited. The audited deaths were purposely sampled for the potential learning value they offered and to diversify lessons learned. According to audit reports, the main contributing factors to malaria deaths included:

delayed presentation by patients, lack of comprehensive assessment and documentation of cases, inadequate care for patients with reduced level of consciousness and shock, inadequate follow-up of patient progress, lack of supportive investigations, and lack of access to renal replacement therapy/dialysis and blood transfusion. The introduction of malaria death audit meetings has added an active, learning platform to complement the use of the malaria death investigation form, and also served as a useful learning tool within Zimbabwe's clinical mentorship program. Regular malaria death audit meetings are potentially useful in improving malaria care and reducing malaria related deaths.

1822

ENHANCING THE PRIVATE HEALTH SECTOR'S ROLE THROUGH ACCESS TO SUBSIDIZED MALARIA COMMODITIES: GAME CHANGER IN BENIN'S SUPPLY CHAIN

Gilbert Andrianandrasana[1], Adjibabi Cherifatou[2], Julie Niemczura de Carvalho[3], Julie Buekens[3], Megan Perry[3], Angelique Gbaguidi[1], Alexis Tchevoede[2]

[1]Accelerating the Reduction of Malaria Mortality and Morbidity (ARM3), Medical Care Development International (MCDI), Cotonou, Benin, [2]National Malaria Control Program, Ministry of Health Benin, Cotonou, Benin, [3]Medical Care Development International (MCDI), Silver Spring, MD, United States

As much as 60% of Benin's malaria cases are diagnosed in the private health sector, where 70% of all antimalarials are also purchased, yet historically, the private sector has not adhered to national malaria diagnosis and treatment guidelines and has faced challenges with maintaining adequate stock-levels of malaria commodities. To enhance the private sector's role reducing malaria morbidity and mortality, we conducted a study of market preferences and a pilot activity to introduce subsidized malaria commodities at selected private health facilities in Benin. We administered a semi-structured questionnaire to 38 key informants from the public and private sectors, including 20 private clinics (8 medical clinics, 6 medical cabinets, and 6 antenatal care centers in Atlantique/Littoral, Borgou/Alibori and Zou/Collines). We found that the private health sector was amenable to complying with Ministry of Health (MOH) norms and wanted to integrate their malaria commodity needs into the national quantification: 56% of private sector stakeholders interviewed preferred the public supply chain, while only 18.8% preferred direct delivery without a middleman. Most respondents favored the set-up of a formal legal framework to be implemented via an MOU between the National Malaria Control Program and accredited entities. Sixty percent of entities were willing to provide public malaria commodities for free, while 13.3% only agreed to do so if they were compensated by the MOH. In 2017, we implemented a pilot activity introducing subsidized malaria commodities in 4 health zones via 145 private health facilities and pharmacies. Private sector staff were trained on the national guidelines, supervision, the national supply chain management system, and disease surveillance reporting before receiving supplies. To date, 102 of the 145 accredited private entities have complied with national guidelines, reporting and respecting the sale price of subsidized malaria commodities. Challenges remain, however supplying subsidized malaria commodities through private facilities and pharmacies has proven to be viable.

1823

EXPANDING THE HEALTH SYSTEM INTO THE FOREST: ANALYSIS AND RESPONSE TO THE CHALLENGE OF PROVIDING MALARIA SERVICES INSIDE FOREST AREAS WITHIN THE GREATER MEKONG SUB-REGION IN THE CONTEXT OF MALARIA ELIMINATION

John Hustedt[1], Sokomar Nguon[2], Kylie Mannion[3], Sam Ossopea[3], Samphornarann Top[2], Linna Khorn[2], Phally Chhun[2], Say Mang[2], Sam An Sen[4], Pisal Heng[4], Po Ly Teng[4], Siv Sovannaroth[4], John Bradley[1], Marco Liverani[1], Colin Ohrt[5], Rohit Singh[6], Luciano Tuseo[7], Say Chy[7], Sergio Lopes[3], Soy Ty Kheang[2], Neeraj Kak[2], Rekol Huy[4]

[1]London School of Hygiene & Tropical Medicine, London, United Kingdom, [2]U.S. Agency for International Development Cambodia Malaria Elimination Project, Phnom Penh, Cambodia, [3]Malaria Consortium, Phnom Penh, Cambodia, [4]National Center for Parasitology, Entomology and Malaria Control, Phnom Penh, Cambodia, [5]Consortium for Health Action, Hanoi, Vietnam, [6]World Wildlife Fund, Phnom Penh, Cambodia, [7]World Health Organization, Phnom Penh, Cambodia

The WHO Strategy for Malaria Elimination in the Greater Mekong Subregion and the Cambodia Malaria Elimination Action Framework note malaria risk is highest in forest or forest fringe areas. From 2006-2016, deforestation increased and the number of confirmed malaria cases decreased 84% from 143,758 to 23,492 (with no change in annual blood examination rates). Simultaneously the percentage of *P. vivax* cases rose from 6 to 50%. Malaria control strategies rely heavily on village-based schemes to provide malaria services. Mobile malaria workers (MMWs) are employed to reach outside villages, but are often located in farms far from forests. Reactive case detection within villages with standard rapid diagnostic tests (the most operationally feasible diagnostic tool) yielded very low test positivity rates (TPR) in Cambodia (<1%), with co-exposed individuals slightly higher at ~3%. Screening data from the USAID Cambodia Malaria Elimination Program (CMEP) of villages with the largest recent case increases (<1%) also suggest most cases are imported from the forest. The Cambodia National Malaria Control Program (NMCP) has pioneered an elimination strategy training those living in forest/forest fringe areas as MMWs. From January-December 2017, the Regional Artemisinin-resistance Initiative empowered local forest residents with MMW training to perform malaria services in Stung Treng Province resulting in 42% TPR with 71% of cases identified as *P. falciparum*. CMEP data shows similarly high TPR rates (36%) from MMWs screening in forest areas of Phnom Kravanh District (70% identified as *P. falciparum*). The Vietnam NMCP piloted a program to identify and treat actual forest transmission *Foci* in Phu Yen Province from 2015-2016. From 2014-2017, this province had the greatest malaria reduction in Central Vietnam (94%). Future efforts should include law enforcement officers (e.g. forest rangers and military) as an epidemiologically important and often neglected populations living in the forest. A rapid scale-up of malaria services into the forest is possible and can improve effectiveness of malaria programs in Cambodia and the Greater Mekong Sub-Region.

1824

THE ROLE OF MOBILE DATA MANAGEMENT SYSTEMS IN MALARIA ELIMINATION IN MYANMAR

Soy Ty Kheang[1], Mie Mie Han[2], Kyawt Mon Win[3], Si Thu Hein[3], Yi Thida[2], Naung Naung[2], Zwe Thu Tun[2], Maung Maung Thwin[2], Taylor Price[4], Neeraj Kak[4]

[1]University Research Co., LLC, Phnom Penh, Cambodia, [2]University Research Co., LLC, Yangon, Myanmar, [3]National Malaria Control Program, Yangon, Myanmar, [4]University Research Co., LLC, Chevy Chase, MD, United States

In the Greater Mekong Sub-region (GMS), Myanmar still has a high burden of malaria. However, Myanmar is committed to eliminating malaria by

2030. Surveillance is a core component of malaria control and elimination and the Ministry of Health and Sports (MOHS) is strengthening the existing data management system for malaria surveillance with support of the Asian Development Bank (ADB). University Research Co., LLC (URC), through ADB, is helping to improve malaria data flow and use from village malaria workers (VMWs), health facilities and private providers in Mon State and Sagaing Region. A pilot project in Mawlamyine, Bilin and Khamti townships uses a malaria case-based reporting (MCBR) mobile application, developed by the National Malaria Control Program (NMCP) and partners, for real time malaria data sharing. In early 2018, the WHO developed a District Health Information System II (DHIS2) application for case-based reporting. The two applications will be synchronized. From November 2017 to January 2018, 78 VMWs and 101 basic health staff (BHS) were trained on the MCBR and DHIS 2 applications, respectively. URC, with the NMCP and partners, developed guidelines on use of the MCBR application for BHS staff and VMWs. The project team conducts regular supervision and monitoring visits with Vector Borne Disease Control (VBDC) staff for VMWs and BHS staff to ensure proper use of the application. After training, supervision and monitoring visits were conducted for 46 VMWs in the three townships. Of them, 89% actively used the MCBR application. All 101 BHS staff trained with the DHIS2 application actively used the application at the March 2018 meeting. From December 2017-March 2018, 2,009 tested persons and 25 positive cases were notified via the applications. BHS staff now report positive cases in real time and VBDC staff take quick action. For instance, in Bilin Township, VBDC staff conducted case investigation and response based on 19 notified positive cases via the DHIS2 application. Overall, real-time notification and quality malaria data are crucial to the NMCP and partners for planning and response in the context of malaria elimination.

1825

REVIEWING THE STATUS OF SOUTH AFRICA'S MALARIA ELIMINATION PROGRAM, AND REVISING THE NATIONAL MALARIA ELIMINATION STRATEGY (2019-2023)

Rebecca Graffy[1], Mbavhalelo B. Shandukani[2], Ednah R. Baloyi[2], Eunice Misiani[2], Wayne Ramkrishna[2], Ryleen Balawanth[1], Craig Davies[1], Oscar Tapera[3], Bheki Qwabe[4], Gillian Malatje[5], Eric Mabunda[6], Lucille Blumberg[7], Yogan Pillay[2], Devanand P. Moonasar[8]

[1]Clinton Health Access Initiative, Pretoria, South Africa, [2]National Department of Health, Pretoria, South Africa, [3]Clinton Health Access Initiative, Boston, MA, United States, [4]KwaZulu-Natal Provincial Department of Health, Jozini, South Africa, [5]Mpumalanga Provincial Department of Health, Nelspruit, South Africa, [6]Limpopo Provincial Department of Health, Tzaneen, South Africa, [7]National Institute for Communicable Diseases, Johannesburg, South Africa, [8]National Department of Health; University of Pretoria, Pretoria, South Africa

In 2012 South Africa drafted its National Malaria Elimination Strategic Plan, with the goal of eliminating malaria from the country's three endemic provinces (KwaZulu-Natal, Limpopo, Mpumalanga) by 2018. Through this period low levels of malaria transmission were successfully sustained (1828 local cases and 5249 total cases in 2012; 1100 local cases and 4252 total cases in 2016) until 2017 when South Africa experienced a malaria outbreak (21882 local and 28529 total cases). In 2018 South Africa has been scheduled to conduct its malaria program review, and revise its National Malaria Elimination Strategic Plan. In this context, the 2017 outbreak has highlighted the need for introspection, and motivated the country to undertake a rigorously data-driven approach to the malaria program review and revision of the elimination strategy. The foundation of the malaria program review will be to consolidate and analyze all existing data in KwaZulu-Natal, Limpopo, and Mpumalanga using the Elimination Checklist. The Elimination Checklist is a tool that has been customized by South Africa to operationalize the World Health Organization's (WHO) 2016 Framework for Malaria Elimination. The Elimination Checklist assigns forty-nine indicators within the 6 strategies recommended by the WHO's framework to assess performance of the program. It evaluates how close the program is to being malaria free, whether all systems are in place to pursue sub-national verification of elimination, and what else is needed to get to zero local indigenous infections. The Elimination Checklist will be completed for each province in May 2018. Gaps identified through the Elimination Checklist will then be prioritized based upon stakeholder consultations and the outputs of an epidemiological-economic model to identify a cost-effective path to malaria elimination. Recommendations will inform the strategic objectives for South Africa's 2019-2023 Malaria Elimination Strategic Plan, which will be drafted from May through August 2018. The tools developed for the malaria program review can subsequently be used by other countries to inform their approach.

1826

MIGRATION PATTERNS AND CARE-SEEKING BEHAVIOR OF VIETNAMESE INTERNATIONAL LABORERS INFECTED WITH MALARIA: A QUALITATIVE STUDY

Kimberly A. Edgel[1], Kristina J. St. Clair[1], Sara E. Canavati[2], Thu M. Nguyen[2], Gerard C. Kelly[2], Thang D. Ngo[3], Duong T. Tran[3], Tho H. Tran[3], Thuy P. Nguyen[4], Nga Nguyen[4], Hoi T. Le[4], Trung V. Nguyen[4], Kinh V. Nguyen[4], Nicholas J. Martin[1]

[1]U.S. Naval Medical Research Unit No. 2, Singapore, Singapore, [2]Vysnova Partners, Inc., Bethesda, MD, United States, [3]National Institute of Malariology, Parasitology and Entomology, Hanoi, Vietnam, [4]National Hospital for Tropical Diseases, Hanoi, Vietnam

In support of Vietnam's malaria elimination goals, there is interest in the threat of imported malaria from Vietnamese citizens returning from international labor, particularly following service in Africa and other Southeast Asian countries where malaria is endemic. A qualitative study was conducted to gain an understanding of patterns of migration as well as behavior and knowledge of returning international laborers during stages of migration. Thirteen in-depth-interviews were conducted at the National Hospital for Tropical Diseases in Hanoi from October 2017 to March 2018 among confirmed malaria patients who recently returned from Africa or Southeast Asia. Information was recorded, transcribed, and translated into English. Analyses included examining, categorizing, tabulating and recombining data. Thematic analysis was undertaken using Nvivo 9® software. Triangulation and critical case analysis added rigor to the process. Most participants traveled from malaria-free regions in Northern Vietnam for employment mainly in Sub-Saharan Africa countries. Lack of malaria knowledge and misconceptions regarding malaria transmission and protective measures were reported. Either no or incorrect protective measures were adopted while abroad. Most participants engaged in high-risk occupations in highly endemic areas. Difficulties accessing the public health system abroad resulted in patients seeking health care in unregulated private sectors. A significant delay in seeking health care in Vietnam on return was observed in most patients likely due to lack of awareness of malaria symptoms. Results highlight risks to malaria elimination associated with international laborers returning to Vietnam from malaria endemic countries. Given the growing Vietnamese international labor force, consideration should be given to appropriate targeted interventions and malaria prevention strategies for this emerging high-risk population group that covers key stages of migration including pre-departure education and awareness, in-country prevention and prophylaxis, and malaria screening on return.

1827

MALARIA ELIMINATION IN LOW INCOME COUNTRIES: DOES IT MATTER WHEN, WHERE, AND HOW WE SLEEP?

Susan F. Rumisha[1], Humphrey D. Mazigo[2], Leonard E. Mboera[3]

[1]National Institute for Medical Research, Dar es Salaam, United Republic of Tanzania, [2]Catholic University of Health and Allied Sciences, Mwanza,

United Republic of Tanzania, [3]Southern African Centre for Infectious Disease Surveillance, Morogoro, United Republic of Tanzania

Long-lasting insecticide treated nets (LLITNs) is the most effectiveness malaria interventions. It has been associated with decline in malaria burden in most sub-Saharan African countries. However, several regions have reported persistence of malaria infection despite high coverage of multiple interventions including LLITNs. Reasons for these observed hotspots are yet to be identified. This study explored the effect of 3-dimension sleeping behaviors namely *when, where,* and *how* on occurrence of malaria in a rural community of Kilosa District, Tanzania. A study assessed occurrence of malaria for members of households as reported by the head. Sleeping behaviors where measured as i) time the person goes under a net (*when*); ii) quality of the house in respect to mosquito entry restriction (*where*); and iii) average sleepers per net (*how*). Principal component analysis was used to construct house quality index using information on building materials; time-to-go-to-net was categorized into 2-hours intervals from 6pm to midnight and average sleepers/net was calculated based on the number of individuals slept in a house by observed nets. Logistic regression models were used to quantify the association. A total of 3,784 individuals were assessed (48.9% males, 58% singles and 60% involved in income generating activity). A quarter (24.3%, n=918) reported to experience malaria during the assessed period (high in females, singles and those with activities). Results indicated a 52% decrease in malaria risk for individuals residing in a good quality house (OR=0.48, 95%CI:0.39-0.59); doubled malaria infection risk when individuals stay inside the house but not under net between 8pm-10pm (OR=2.0, 95%CI: 1.29-3.1); and house quality modified effect of average sleepers, with poor quality houses presented high risk even if few individuals slept in a net (OR=1.4, 95%CI:1.1-1.8, p=0.005). The three sleeping behaviors were highly associated with occurrence of malaria. Results are eye opener to reasons for presence of malaria hotspots in most regions. Communities should be educated on proper utilization of LLITNs to maximize its effect.

1828

IMPLEMENTING MALARIA MASS DRUG ADMINISTRATION: EXPERIENCE FROM A HIGH TRANSMISSION SETTING IN NORTHEASTERN UGANDA

Ronald Mulebeke[1], Fred Bukenya[2], Kathryn Collborn[3], Richard Elliot[4], Thomas Eganyu[2], Wycllif Odude[2], Humphrey Wnazirah[2], Samuel Gonahasa[5], Mary Kyohere[5], Catherine Maiteki[6], Jean-Pierre Van geertruyden[7], Dorothy Echodu[2], Adoke Yeka[1]

[1]Makerere University School of Public Health, Kampala, Uganda, [2]Pilgrim Africa, Kampala, Uganda, [3]University of Colorado Denver, Denver, CO, United States, [4]Boise State University, Boise, ID, United States, [5]Infectious Disease Research Collaboration, Kampala, Uganda, [6]Ministry of Health Uganda, Kampala, Uganda, [7]University of Antwerp, Antwerp, Belgium

Mass drug administration (MDA) is one of the suggested means to accelerate efforts towards elimination and attainment of malaria-free status. There is limited evidence of optimum methods of implementing MDA programme such as promoting community participation and compliance with treatment in low income countries. We describe experience of implementing a population-based MDA using dihydroartemisinin piperaquine (DHAPQ) delivered using a fixed distribution strategy in Kapujan sub-county, an area of high malaria transmission in North Eastern Uganda. MDA was implemented in a study to assess the impact of population based MDA in combination with indoor residual spraying (IRS) and IRS alone in a high transmission setting in Uganda. Four rounds of interventions are planned over a period of two years at six months intervals. A baseline housing and population census was conducted in the target area to establish the eligible population. Household members were screened and eligible participants consented for MDA. A database for all eligible persons was created. The population was sensitized at all levels through meetings, and use of mass media. Established village meeting points were used as MDA distribution sites at every village such as, schools, sub-county headquarters and village meeting centers. A team of 19 personnel comprising health workers, data officers and community resource personnel conducted the exercise at each distribution site for 4 days in 18 villages over a total period of 15 days. The first dose of DHAPQ was directly observed on site. Health workers were used to follow up participants to monitor completion of the second and third doses. With a baseline population of 14,468 people living in 2490 households, MDA coverage of 85% was achieved for the first round and 75.5% for the second round. Adherence to all three doses of treatment in the second round of interventions was 76.5% for first dose, 75.02% for second dose and 75.00% for third dose. Using community structures facilitates community participation and adherence to MDA. The best timing of the distribution is when school children were for holidays and during the dry season.

1829

OPERATIONALIZING MALARIA ELIMINATION BY STEPS/ COMPONENTS: THE CASE OF ZAMBIA

Kafula Silumbe[1], Busiku Hamainza[2], Elizabeth Chizema-Kawesha[2], Anthony L. Yeta[2], Mutinta Mudenda-Chilufya[2], Duncan Earle[1], John M. Miller[1], Richard W. Steketee[1]

[1]PATH Malaria Control and Elimination Partnership in Africa (MACEPA), Lusaka, Zambia, [2]National Malaria Elimination Centre, Zambia Ministry of Health, Lusaka, Zambia

The Zambia National Malaria Elimination Program (NMEP) has recorded a number of successes in reducing malaria transmission across the country in the last decade; Zambia has now set a national target of eliminating malaria by 2021. The call to eliminate malaria requires high coverage and use of a full package of interventions including vector control (long lasting insecticidal nets [LLINs] and indoor residual spraying [IRS] with insecticide rotation) and passive and active case detection and prevention (confirming cases with rapid diagnostic tests [RDTs] or microscopy and treating with artemisinin combination therapy [ACTs] and targeting reactive case detection (RCD) and population-wide mass drug administration [MDA] to specific areas). Building on existing district and health facility teams, the NMEP trained new community health workers (CHWs) and retrained existing CHWs to effectively confront malaria in their communities. Between 2015 and 2018, more than 3,000 CHWs were trained in passive and active case detection in 4 of 10 provinces and more than 2,000 were trained in MDA activities in Southern and Western provinces. CHWs trained in MDA have treated 484,044 people in the past 3 years and, in 2018, approximately 50% of all confirmed malaria cases were reported by trained CHWs; as a result, in Southern Province, malaria cases reported from the health facilities have decreased by 85% and substantially reduced the patient load at facilities. Creating the workforce for malaria elimination has required a consultative and coordinated approach by the NMEP guided by data generated from the health care delivery system. We will review 2018 case data and malaria indicator survey data to assess current progress and needed workforce expansion to operationalize the 2021 elimination plan.

1830

INCREASE IN OUTDOOR BITING IN PRIMARY AND POTENTIAL SECONDARY VECTORS: POSSIBLE IMPLICATIONS FOR MALARIA ELIMINATION

Kochelani Saili[1], Busiku Hamainza[2], Elizabeth Kawesha-Chizema[2], John M. Miller[1], Javan Chanda[1]

[1]PATH Malaria Control and Elimination Partnership in Africa (MACEPA), Lusaka, Zambia, [2]National Malaria Elimination Centre, Zambia Ministry of Health, Lusaka, Zambia

Since the early 2000s, Zambia's Ministry of Health has successfully scaled up the mass distribution of long lasting insecticide-treated nets (LLINs) and targeted indoor residual spraying (IRS) in an effort to mitigate the burden of the disease. The success of both methods depends on robust entomological surveillance, and, as the country strives to eliminate

malaria by 2021, monitoring the presence of potential vectors and outdoor biting is critical Conducted in the rural areas of Sinazongwe and Siavonga districts in southern Zambia between February-April and September-November 2017, this study evaluated indoor and outdoor mosquito foraging behavior using Centers for Disease Control light traps, indoor resting density using pyrethrum spray catches (PSC), and mosquito feeding behavior using human landing catches (HLC). Of the 2,681 female *Anopheles* mosquitoes caught by indoor and outdoor light traps and PSC, 61% were identified as malaria vectors (*An. gambiae s.l.* and *An. funestus s.l.)*, a slight increase from what has been observed in the two previous years of entomological monitoring. A total of 1,073 mosquitoes, made up mainly of *funestus* (n= 859; 80.1%) and *gambiae* (n= 183, 17%), were captured using HLC. Analysis of biting times showed that most biting took place outdoors for *An. gambiae s.l.* (62%) and *An. funestus s.l.* (65%) with no significant difference in outdoor verses indoor biting rates in either species. The heterogeneity in the biting pattern suggests that malaria transmission may be predominantly taking place outdoors and in the early evenings by both *gambiae* and *funestus* and that malaria elimination programs should consider developing interventions that target both indoor and outdoor vectors. This study also documents the presence and diversity of potential secondary vectors, which may prove to be epidemiologically important as control efforts are focused on the primary vectors.

1831

STRENGTHENING MALARIA SURVEILLANCE IN A HIGH TRANSMISSION REGION OF HAITI: FEASIBILITY OF DHIS2-BASED INDIVIDUAL MALARIA CASE REPORTING AT THE HEALTH FACILITY LEVEL

Alyssa J. Young

Clinton Health Access Initiative, Boston, MA, United States

Malaria elimination in Haiti is achievable, however improvements in surveillance system structure are required to ensure that individual case data are comprehensively and systematically captured and used to inform elimination activities. In December 2017, Haiti introduced DHIS2 individual case reporting by health facility staff in 11 health facilities in the department of Grand Anse, which has reported at least 40% of the country's annual malaria case burden since 2015. New case notification forms were designed for ease of data collection and entry and included questions to help to classify cases, understand transmission dynamics and parasite mobility, and evaluate social and behavioral risk factors to better inform interventions. Data are recorded on paper forms during patient consultation and later recorded in the DHIS2 Tracker module using an electronic version of the same paper form. Tablets and internet access were provided to health facilities for reporting into DHIS2. Each week, surveillance officers validate data at the health facility by comparing DHIS2 data with paper forms and morbidity and laboratory registries. Indicators such as data completeness (key patient indicators reported) and timeliness (data entered and synced within 24 hours of diagnosis) are used to monitor progress and success of DHIS2 reporting. In the first three months of implementation and across all health facilities, 62% of DHIS2 reports were considered complete, though this varied by week from 30.7% to 92.6%. Timeliness of reporting rates were not as high (28.1% of all cases were reported within 24 hours of diagnosis), due to issues with internet connectivity. Results and interviews with end users indicate that with improvements in connectivity, DHIS2 case-based reporting is feasible and can help to strengthen facility-based surveillance. Recommendations are to provide additional on-site support and evaluate timeliness of reporting using a timeline of one week as opposed to 24 hours. Future plans include expansion to an additional 29 health facilities in the same department, and building capacity for data use and integration with other data systems.

1832

TARGETED REACTIVE INVESTIGATIVE APPROACHES AT REMOTE AREA SLEEPING SITES TO INTERRUPT MALARIA TRANSMISSION IN VIETNAM

Sara E. Canavati[1], Cesia E. Quintero[1], Thang D. Ngo[2], Colin Ohrt[1], Thuan V. Vo[1], Duong T. Tran[2], Gerard C. Kelly[1], Nicholas J. Martin[3]

[1]Vysnova Partners, Inc., Bethesda, MD, United States, [2]The National Institute of Malariology, Parasitology and Entomology, Hanoi, Vietnam, [3]U.S. Naval Medical Research Unit No. 2, Singapore, Singapore

Vector and epidemiological complexities in the Greater Mekong Subregion (GMS) present significant challenges to malaria elimination efforts, particularly in consideration of forest malaria and the increasing threat of drug-resistant malaria. In 2016, a cross-sectional study was conducted using a novel targeted reactive investigative approach at remote area sleeping sites in Phu Yen Province Vietnam. Investigators gathered data on confirmed malaria cases at remote area sleeping sites, characterized common local remote area sleeping site settings and identify malaria prevention and risk behaviors of those frequenting the areas. One-hundred and ten confirmed malaria patients were identified as index cases and interviewed at the suspected site, where transmission was suspected to have occurred at a forest or forest-fringe farm sleeping site. An additional 187 individuals sleeping within 500m of the suspected transmission sites were also interviewed. Logistic regression models were used to calculate Prevalence Odds Ratios (PORs) and 95% Confidence Intervals (CI) for risk factors for being an index case. 82% of index cases were males with a mean age of 36.6 years. Among 93 participants who slept in the forest, index cases frequently did not use nets (POR=2.95; 95% CI 1.26–6.92) and were less likely to use insecticide treated nets (ITNs) (adjusted-POR=0.10; 95% CI 0.02–0.58). Index cases were also more likely to work after dark (adjusted POR=6.33; 95% CI 1.92–20.9). A significantly higher proportion of forest index cases worked in natural resource occupations (hunting, trapping) (POR=11. 7; 95% CI 4.37–31.2). Of 204 respondents who slept on a farm, ITN use was not significantly different between index cases and neighbors. A significantly higher proportion of index cases were involved in planting or logging on farms (POR=2.74; 95% CI 1.27–5.91). Results from this study identify common risk behaviors among forest goers with a history of malaria, and speak towards appropriate targeted interventions and educational strategies.

1833

MULTIPLE APPROACHES FOR MALARIA CASE MANAGEMENT IN THE STRUGGLE TO REACH PRE-ELIMINATION OF MALARIA

Goodluck Tesha[1], Zahra Mkomwa[1], Jasmine Chadewa[2], Lusekelo Njoge[2], Sigsbert Mkude[3], Dunstan Bishanga[2], Chonge Kitojo[4], George Greer[4]

[1]PATH, U.S. Agency for International Development Boresha Afya Project, Dar es Salaam, United Republic of Tanzania, [2]Jhpiego, U.S. Agency for International Development Boresha Afya Project, Dar es Salaam, United Republic of Tanzania, [3]National Malaria Control Program, Tanzania Ministry of Health, Dar es Salaam, United Republic of Tanzania, [4]US President's Malaria Initiative, United States Agency for International Development, Dar es Salaam, United Republic of Tanzania

While Tanzania remains a high malaria burden country, recent progress has been made along the pathway to elimination. Malaria Indicator Surveys have shown that prevalence has halved from over 30% to less than 15% in the last 15 years, regions with extremely low prevalence (<1%) increased from 1 in 2008 to 7 in 2016, and the proportion of population living in low transmission areas (<10% prevalence) has increased from 31% in 2000 to 49% in 2015. Since 2016, the 5-year USAID Boresha Afya Project has worked in 1817 facilities in the 7 regions of the Lake/Western Zone, where according to 2016 MIS data, malaria prevalence remains

high. Boresha Afya has collaborated with the NMCP to to support the goal of a reduction in malaria case fatality rate to below 1% by 2020 through promotion of universal access to early diagnosis and prompt treatment, and provision of preventive therapies to vulnerable groups. Strategies have been implemented including training providers on quality testing using mRDT, stratification of malaria burden using GIS mapping, introduction of malaria service and data quality improvement, and outreach programs to remote areas. In project regions since 2016 there has been provision of access to appropriate and timely malaria diagnosis to at least 90% of suspected malaria cases. Additionally, as of February 2018, a decrease in clinical malaria cases have been observed from 9% in 2016 to 2% (national level 3%), mRDT testing has increased from 75% in 2016 to 88%, and use of blood slide microscopy has decreased from 16% in 2016 to 10%. As project activities proceed, we have also observed improved quality (completeness, consistence and timeliness) of malaria indicator data within the routine health information system and improved use of data for decision making by providers. To support progress towards malaria elimination, Boresha Afya will focus on improved testing of suspected cases at facility level and prompt treatment of positive cases to promote rational use of antimalarials, as well as additional community outreach activities to increase access to malaria case management in remote areas, and employment of GIS mapping to rapidly target services.

1834

ELECTROCARDIOGRAPHIC SAFETY EVALUATION OF REPEATED COURSES OF DIHYDROARTEMISININ-PIPERAQUINE FOR USE IN MASS DRUG ADMINISTRATION

Pere Millat-Martínez[1], Rhoda Ila[1], Moses Laman[2], Leanne Robinson[3], Harin Karunajeewa[4], Camila González-Beiras[1], Haina Abel[5], Kevin Pulai[5], Sergi Sanz[6], Laurens Manning[7], Brioni Moore[8], Quique Bassat[6], Oriol Mitjà[6]

[1]Lihir Malaria Elimination Programme, Londolovit, Lihir Island, NIP, Papua New Guinea, [2]PNG Institute Medical Research, Madang, Papua New Guinea, [3]Burnet Institute, Melbourne, Australia, [4]WEHI, Melbourne, Australia, [5]Lihir Medical Centre, Londolovit, Lihir Island, NIP, Papua New Guinea, [6]ISGlobal, Barcelona, Spain, [7]UWA, Melbourne, Australia, [8]Curtin University, Melbourne, Australia

Repeated rounds of Mass Drug Administration (MDA) of antimalarial drugs is a modern approach to eliminate malaria. Dihydroartemisinin-Piperaquine (DHA/PQP) is an effective, well tolerated and long-acting antimalarial suitable for MDA. We assessed the cardiac safety of repeated treatment courses with DHA/PQP. METHODS: We conducted an interventional cohort study in Lihir Island, Papua New Guinea from Sept 21 to Dec 21, 2015. Consenting healthy volunteers were enrolled for repeated treatment with standard 3-day course of DHA/PQP 2.1/17.1 mg/Kg daily given monthly over 3 months. Eligible participants were healthy individuals aged 3 to 60 years. Triplicate twelve-lead ECG readings were conducted with an ELI 150 Cardiograph® at pre-dosing and 4h after the third dose of treatment with each monthly course. Interpretation of the tracings was independent and centralized at a cardiac laboratory. The primary endpoint was QTc prolongation from baseline to the 4h post-dosing ECG; safety was assessed comparing the difference in prolongation of the third course post-dosing ECG and the first course post-dosing ECG. Of 84 enrolled participants, 69 (82%) completed all treatment courses and ECG measurements. In the primary analysis, the mean increase in QTcF was 17.1ms (SD 17.1) in the third course post dosing ECG compared with 19.6ms (SD 17.8) in the first course post dosing ECG (risk difference -2.4 [95%CI - 6.9 to 2.1], p-value=0.285). We recorded QTcF prolongation >60 ms from baseline in 2 (2.9%) participants after the third course, compared to 3 (4.3%, p-value=1.00) after the first course. None of the participants had QTcF intervals >500ms. Three repeated courses of DHA/PQP given monthly are as safe as single course. DHA/PQP could be administered in consecutive monthly courses as part of elimination strategies, with no increased or cumulative risks in comparison to single course.

ASSESSING AND ENHANCING DIGITAL SOLUTIONS FOR MALARIA ELIMINATION

Lakshmi Balachandran[1], Anne Liu[1], Pedro Pagalday Olivares[1], Sameen Babur[1], Juan Manuel Alcantara Acosta[2], Jose García Muñoz[2], Rodolfo Melia[2], Karoline Tufte Lien[2], Derek Treatman[3], Egwuma Efo[3], Tim Nichols[3], Abdisalan Noor[4], Arnaud Le Menach[1]

[1]Clinton Health Access Initiative, Boston, MA, United States, [2]University of Oslo, Oslo, Norway, [3]Vital Wave, Palo Alto, CA, United States, [4]World Health Organization, Geneva, Switzerland

Surveillance systems are the backbone of malaria elimination programs, providing information on where and how transmission is occurring and how interventions should be targeted. However countries face substantial technical challenges in rolling out integrated case-based information systems that collect timely, high quality data and facilitate appropriate decision making for elimination. To address these technical challenges, a partnership of organizations (Clinton Health Access Initiative, University of Oslo, Vital Wave, and World Health Organization) assessed existing surveillance systems in order to identify gaps that can be addressed with enhancements to DHIS2 (the de-facto malaria information system in many countries) and selected mobile tools. To inform technical requirements for software development, in-depth interviews with malaria programs, end users, and technology experts were conducted globally and in three regions - Greater Mekong Sub-region, Sub-Saharan Africa, and Mesoamerica. Initial findings emphasize the importance of user-friendly mobile interfaces suited for low connectivity contexts, as malaria cases happen infrequently in elimination settings, thus limiting familiarity with technical tools. Users would also like to see basic dashboards on mobile tools for performance tracking; dashboards that overlay information from different sources such as case data, breeding sites, *Foci* boundaries, and response interventions; and alternative mechanisms for accessing online dashboards and reports (i.e. email, WhatsApp). Finally, insufficient resources for surveillance may warrant need for digital tools that support optimal resource allocation and task management. With the consolidation of the findings and requirements for software development, enhanced features will be developed on DHIS2 and mobile applications for case notification, investigation, *Foci* investigation, and response activities, over the coming months. These solutions will be user tested, piloted, and rolled out in ten countries across regions to strengthen existing surveillance systems.

1836

LOW RISK OF SUDDEN UNEXPLAINED DEATH AFTER DIHYDROARTEMISININ-PIPERAQUINE: A SYSTEMATIC REVIEW AND BAYESIAN META-ANALYSIS

Xin Hui S. Chan[1], Yan Naung Win[1], Laura Mawer[1], Jireh Tan[1], Josep Brugada[2], Nicholas J. White[1]

[1]Mahidol-Oxford Tropical Medicine Research Unit, Faculty of Tropical Medicine, Mahidol University, Bangkok, Thailand, [2]Hospital Clinic, August Pi i Sunyer Biomedical Research Institute (IDIBAPS), University of Barcelona, Barcelona, Spain

Dihydroartemisinin-piperaquine (DHA-PPQ) is a highly effective and well-tolerated artemisinin-based combination therapy which has been evaluated extensively in the prevention and treatment of malaria. Piperaquine, like several structurally-related antimalarials currently deployed, can prolong cardiac ventricular repolarisation duration and the electrocardiographic QT interval, leading to concerns about its proarrhythmic potential. We conducted a systematic review and meta-analysis to assess the risk of potentially lethal iatrogenic ventricular arrhythmias in subjects receiving DHA-PPQ. We searched multiple databases, last on 24 May 2017, for studies of DHA-PPQ in humans. Further unpublished studies were identified with the WHO Evidence Review Group on the Cardiotoxicity of Antimalarials. Prospective randomised-controlled trials or cohort studies in which subjects received at least one 3-day treatment course of DHA-

PPQ for mass drug administration (MDA), preventive therapy, or case management of uncomplicated malaria, with follow-up over at least three days were eligible. The risk of sudden unexplained death (SUD) after DHA-PPQ with 95% credible intervals generated by Bayesian meta-analysis was compared with the baseline rate of sudden cardiac death (SCD). Among the 197,867 individuals who received DHA-PPQ in 94 studies: 154,505 in MDA, 15,188 as repeated courses in preventive therapies and case management, and 28,174 as single-course treatments of uncomplicated malaria there was one potentially drug-related SUD. The median pooled risk estimate of SUD after DHA-PPQ was 1 in 757,950 (95% CI: 1 in 2,854,490 to 1 in 209,114). This is not higher than the baseline rate of SCD. DHA-PPQ is associated with a very low risk of sudden unexplained death. Concerns about drug-related repolarisation-related cardiotoxicity need not limit its current use.

1837

PUTTING EVOLUTION IN ELIMINATION: WINNING OUR ONGOING BATTLE WITH EVOLVING MALARIA MOSQUITOES AND PARASITES

Silvie Huijben, Krijn P. Paaijmans

Arizona State University, Tempe, AZ, United States

Malaria elimination efforts rely heavily on antimalarial drugs and insecticide-based interventions, with artemisinin-based combination therapies, indoor residual spraying and long-lasting insecticidal nets being the cornerstones of malaria treatment and prevention. However, resistance has emerged against nearly every antimalarial drug and insecticide that is available. Here we discuss the evolutionary consequences of the way we currently implement antimalarial interventions, how this may facilitate the evolution of resistance, and how evolutionary principles can be applied to extend the lifespan of current and novel interventions. We argue for a need of greater understanding of general evolutionary principles, for public health in general and for malaria elimination programs in particular, to develop improved resistance management strategies for sustainable malaria control and ultimately elimination.

1838

MALARIA PREVALENCE AMONG ASYMPTOMATIC PARTICIPANTS DURING MALARIA CASE MANAGEMENT PROMOTION CAMPAIGN IN THE PRIVATE SECTOR IN KINSHASA, DEMOCRATIC REPUBLIC OF THE CONGO.

Solange E. Umesumbu[1], Yolande Bongonda[1], Charlie Baseane[1], Marcel Lama[2], Albert Albert Mudingayi[2], Thierry Bobanga[3], Joris Likwela[4]

[1]National Malaria Control Program, Kinshasa, Democratic Republic of the Congo, [2]ASF / PSI / Defeat Malaria, Kinshasa, Democratic Republic of the Congo, [3]Medicine Tropical Department, University of Kinshasa, Kinshasa, Democratic Republic of the Congo, [4]University of Kisangani, KIsangani, Democratic Republic of the Congo

Considering the high malaria prevalence variability in the prevalence, NMCP took the opportunity to analyze the asymptomatic carriage of this parasite to generate data that could update the estimation of the malaria burden in Kinshasa population. Opportunity to promote "ACTs with Green Leaf" in the private sector. This campaign was organized by ASF / PSI as part of the Defeat Malaria project. A cross-sectional survey was carried out among 2062 volunteers during August 2016. This period corresponded to the end of the dry season and the beginning of the rainy season in Kinshasa. SD BIOLINE Malaria Antigen Pf/Pan Rapid Diagnostic Test was used for testing. Age and sex were collected and analyzedMean age of the participants was 26.2 years. It appears that the majority of volunteers were adults over 26 years and male. The sex ratio (men: women) was therefore 1.37. The total of RDTs positive was 14.7% IC 13-17%. Prevalence in age group was respectively 20,8%; 19,4%; 18,2% and 9,2% for 0-5 years , 6-15 years, 16-25 years and up to 26 years. In conclusion, the prevalence of asymptomatic malaria is high in Kinshasa population. The program should continue prevention activities, in this case the Long Lasting Insecticidal Net (LLIN) campaign, as well as the promotion of control measures.

1839

STRATIFICATION FOR MALARIA ELIMINATION USING LIMITED DATA

Caitlin A. Bever[1], Josh Suresh[1], Jaline Gerardin[1], John M. Miller[2], Busiku Hamainza[3], Thom Eisele[4], **Edward A. Wenger**[1]

[1]Institute for Disease Modeling, Bellevue, WA, United States, [2]PATH MACEPA, Lusaka, Zambia, [3]National Malaria Elimination Centre, Lusaka, Zambia, [4]Tulane University, New Orleans, LA, United States

National malaria control programs must decide which interventions to implement where, in a manner that maximizes disease impact within budgetary constraints. This spatial targeting of interventions, or stratification, is often further complicated by a limited availability of data to inform the decisions. Previously, we used a detailed mathematical model of malaria in the Lake Kariba region to identify that population clustering, historical transmission intensity, and importation rates are key quantities for determining the interventions required to achieve elimination. While these metrics are themselves difficult and expensive to measure, here we show how they can be substituted with proxies in the form of settlement maps (from satellite imagery) and routine incidence reports. Both of these data sources are readily available in many endemic countries. We demonstrate the application of our approach to the stratification of all of Southern Province, Zambia, and discuss how the method may be extended to other regions of Zambia and beyond.

1840

VOICES FROM THE FRONT LINE: RESULTS FROM INTERVIEWS WITH EMPLOYEES AT WORKSITES IN HIGH-MALARIA BURDEN DISTRICTS REGARDING MALARIA AWARENESS AND PRACTICES

Quoc Tuan Nguyen[1], Stephen Poyer[2], Dr. Tran Thanh Duong[3], Josselyn Neukom[1]

[1]Population Services International-Vietnam, Hanoi, Vietnam, [2]Population Services International, Washington, DC, United States, [3]National Institute of Malaria, Parasitology and Entomology, Hanoi, Vietnam

In Vietnam, malaria transmission is highest in rural, forest areas in the central/southern regions along the Cambodia and Lao borders. An estimated 4 million people live in high burden districts within the 4 provinces covered by PSI's malaria programming: Gia Lai, Binh Phuoc, Dak Lak and Quang Binh. In 2017, the National Malaria Program reported 4,548 confirmed cases—an increase over 4,161 confirmed cases in 2016. Worksites within/near the forest are presumed transmission hot spots, although data regarding the location/type of worksites and malaria care was lacking in Vietnam. To address this evidence-gap, PSI collaborated with government partners to list 12,633 worksites of all types and sizes, which was 14 times higher than the official number of worksites registered in the same areas (893). PSI then mapped 158 worksites with at least 50 workers and of four priority types, of which 20 were prioritized to receive onsite malaria programming. To better understand the health needs among workers at risk of malaria, PSI interviewed 155 workers at 5 sites in January 2017. Workers at these sites reported seeking care for fever from a district/provincial hospital (60%), commune health station (51%) and private clinic (24%). Only 1 in 3 workers interviewed reported awareness that a rapid diagnostic test (RDT) for malaria exists and only 60% of workers who had a fever reported receiving a malaria test of any type. Less than 1 out of 4 (23%) workers interviewed knew where to find RDT. 81% of workers knew that treated bednets prevent malaria, but only 2% are aware of treated hammocks. Only 24% of bednets used by workers in the previous night were treated with insecticide. The most common health concerns among workers interviewed were fever (84%), malaria

(43%), digestive or respiratory illnesses 20%) and dengue (13%.) While concern about fever was high, only half of interviewees were aware that fever is a common symptom of malaria. Data collected from workers at high-risk worksites indicates a need to improve access to and motivate use of malaria information, products and services to reduce worker risk and achieve the Ministry of Health's goal to eliminate malaria by 2030.

1841

UNDERSTANDING THE DRIVERS AND DETERMINANTS OF AN EFFECTIVE MALARIA RESPONSE IN A CHALLENGING OPERATING ENVIRONMENT: THE BURUNDI CASE STUDY

Walter M. Kazadi

World Health Organization, Bujumbura, Burundi

Between 2010 and 2017, Burundi has continued to report increases in malaria incidence and related deaths, whilst the African region reported 20% reduction. Retrospective review suggests that malaria incidence has been steadily increasing since 2005. The most significant deterioration occurred between 2014 and 2017, even as the available funding for malaria operations reached its pick in 2015, before dropping dramatically in 2016. Indeed, malaria incidence skyrocketed from 47/1000 in 2014 to 815/1000 at risk population in 2017, a near twenty-fold increase, coinciding with the end of the national malaria strategic plan 2013-2017, and the first year after the endorsement by the country of the Global Technical Strategy 2016-2030 and the African Malaria Strategy as the planning and implementation framework. Malaria related deaths followed same trends, reaching over 4,000 cases in 2017 alone. The malaria outbreak was only officially declared in March 2017. The official declaration paved the way to the initiation and implementation of a multi stakeholder response under the leadership of the Ministry of Public Health and HIV/AIDS, with support from WHO, USAID, the Global Fund, the World Bank and other Partners. The outbreak was brought under control for the first time and declared over in December 2017, when overall incidence crossed the WHO epidemic threshold. Reported incidence has continued to decline, but a closer look at the core areas of focus related to lessons learned from eradication era highlights systemic deficiencies in malaria surveillance, early warning and response, weak community engagement, and outdated malaria policies, as well as lack of collaboration with research institutions. In-depth policy reviews combined with customized approach to surveillance can revolutionize malaria control efforts and may provide the clue to putting the country back on track towards malaria elimination, thus contributing to eradication efforts.

1842

PREPARING FOR THE NEXT GLOBAL THREAT - A CALL FOR TARGETED, IMMEDIATE DECISIVE ACTION IN SOUTHEAST ASIA TO PREVENT THE NEXT PANDEMIC IN AFRICA

Colin Ohrt[1], Thang D. Ngo[2], Thieu Q. Nguyen[2], The supporting NIMPE and Provincial Health teams[2]

[1]Consortium for Health Action, Savage, MN, United States, [2]National Center for Parasitology Entomology and Malaria Control (NIMPE), Hanoi, Vietnam

Global investments have had great impact on malaria - these are now at risk of being reversed. Cambodia is where drug resistance historically emerges and spreads globally to drive resulting pandemics - we are currently watching history repeat itself. Despite large investments and recent success in driving down overall rates of malaria, high levels of resistance to nearly all antimalarial drugs are now widespread in Cambodia. Malaria cases are again rising in both Cambodia and Vietnam. Nearly incurable malaria in this region is a real and present threat. Critical actions to prevent further spread of the emerging incurable parasites are: 1) Commitment and real sense of urgency through declaration of a "Public health emergency of international concern" or a similar set of directives; 2) Establish leadership with sufficient authority, respect, expertise and operational funding; 3) Engage affected security forces to stop disease transmission and support elimination operations; 4) Utilize surveillance as a core intervention with result-based funding targeting malaria transmission *Foci* with rapid and effective action. Immediate decisive action is needed in Southeast Asia to prevent the next malaria pandemic. This presentation highlights persistent gaps in the region with methods to address them. Our 2015-6 collaboration with NIMPE pilot tested tools needed to intervene in actual forest transmission *Foci*. Our study district saw a 96% decrease in malaria from 2014-2017, with the entire province seeing the largest decrease in Central Vietnam in this same timeframe. We describe methods to tackle transmission *Foci*, with both an integrated prevention and treatment package and update the audience to the continuously evolving situation in SE Asia. We will call on all stakeholders to make critical changes to current investments to address this critical challenge.

1843

EVALUATING THE FEASIBILITY AND ACCEPTABILITY OF INTEGRATING NOVEL APPROACHES TARGETING HIGH RISK POPULATIONS INTO ROUTINE PROGRAM ACTIVITIES IN ACEH PROVINCE, INDONESIA

Chris Cotter[1], Jennifer L. Smith[1], Martha G. Silaen[2], Jerry O. Jacobson[1], Iqbal R. Elyazar[3], Farah N. Coutrier[2], Adam Bennett[1]

[1]Global Health Group at the University of California San Francisco, San Francisco, CA, United States, [2]Eijkman-Institute for Molecular Biology, Jakarta, Indonesia, [3]Eijkman-Oxford Clinical Research Unit, Jakarta, Indonesia

In Aceh Province, Indonesia, where malaria transmission is primarily associated with occupational exposure such as forest work, epidemiological studies are being conducted to identify risk factors and interventions for high-risk populations and to test novel reactive case detection (RACD) approaches in forest-going groups. Operational research can provide national malaria programs with important evidence to improve program policies and activities, yet there may be barriers to implementing these approaches in a programmatic setting. A prospective case-control study and evaluation of routine household RACD compared to socio-behavioral RACD (venue-based and peer-referrals) were carried out between April 2017 and September 2018 in Aceh Besar and Aceh Jaya districts. In order to determine the operational feasibility and acceptability of these approaches to be integrated into routine program activities, an evaluation will be conducted prior to the study end in September 2018. Qualitative methods including semi-structured interviews and focus group discussions will be implemented with health facility and surveillance staff from the four study subdistricts, study personnel, and other key decision-makers within the program. This evaluation will capture information on field operations related to the case-control and socio-behavioral RACD studies including transportation, communication, sample collection, processing and transport, conducting interviews, treatment follow-up, training, and costs. By evaluating the feasibility and acceptability of these approaches, the national malaria program in Indonesia will be better equipped to integrate these evidence-based approaches into routine surveillance to target high-risk populations.

1844

A HEALTH COMMUNICATION PACKAGE TO INCREASE DRUG ADHERENCE AMONG VIVAX MALARIA PATIENTS WITHOUT G6PD DEFICIENCY ON THE INTERNATIONAL BORDERS OF NORTHERN THAILAND

Nardlada Khantikul[1], Aungkana SaeJeng[1], Prayuth Sudathip[2], Rungrawee Tipmontree[2], Suravadee Kitchakarn[2], Jintana Chaiwan[1], Surachet Aurnothong[1]

[1]Office of Disease Prevention and Control Region 1, Department of Disease Control, Ministry of Public Health, Chiang Mai, Thailand, [2]Bureau

of Vector Borne Disease, Department of Disease Control, Ministry of Public Health, Nonthaburi, Thailand

Thailand's national treatment guideline for treatment of uncomplicated vivax malaria is a 3-day chloroquine (blood schizontocide) and 14 days of primaquine (tissue schizontocide). Previous retrospective study of patients in Mae Sarieng and Muang districts of Mae Hong Son Province, showed up to 76% of 206 vivax patients reported varying degree of non-adherence to the treatment guidelines, as reported previously. More recent clinical trials along the western borders of Thailand showed that *Plasmodium vivax* patients who self-administered treatment showed higher non-adherence rate and e compared to patients who received directly-observed treatment (DOT), as reported previously. We developed a new health communication package aim to improve treatment adherence in vivax patients with normal glucose-6-phosphaye dehydrogenase enzyme (G6PD) in northern Thailand. Information from previous studies on patient's drug adherence behavior and participation from the local malaria clinical staff were incorporated in the development of the health communication package. The format and contents were tailored to target the communities in northern Thailand, including hill tribe communities and cross-border migrants from Myanmar. Thirty-six *vivax* patients diagnosed in malaria clinics in Mae Hong Son province from January to March 2015 provided interviews before and after introduction the communication package. Patients were given a G6PD fluorescence spot test (FST) prior to receiving treatments according to the national guidelines along with health communication package. Exit interview were conducted during the follow-up visit to determine patient's treatment adherence behavior. The majority of the patients 83.3% (30 out of 36) complied with drugs correctly and followed the guideline of treatment program of the clinics. The average scores on knowledge and perception of malaria and malaria treatment were significantly higher than the scores before the implementation ($p< 0.05$). Our results showed targeted health communication package can help improve patient's understanding and adherence to vivax treatment.

1845

ADAPTING REACTIVE CASE DETECTION FOR MALARIA IN FOREST WORKERS IN ACEH, INDONESIA

Adam Bennett[1], Jennifer L. Smith[1], Jerry Jacobson[1], Martha Silaen[2], Chris Cotter[1], Iska Zarlinda[2], Cut Maneh[3], Abdul Fatah[4], Rintis Noviyanti[2], Farah Coutrier[2], Iqbal Elyazar[2]

[1]University of California San Francisco, San Francisco, CA, United States, [2]Eijkman Institute for Molecular Biology, Jakarta, Indonesia, [3]Provincial Health Laboratory, Banda Aceh, Indonesia, [4]Provincial Health Office, Banda Aceh, Indonesia

Reactive case detection (RACD) is conducted by many malaria elimination programs to detect and treat infected individuals living in close proximity to an index case presenting to a health facility or community health worker. However, in settings where the risk of malaria infection is primarily due to occupational exposures such as forest work, there may be minimal spatial clustering of infections, limiting the utility of RACD approaches that rely on geographic proximity. We evaluated a novel RACD strategy in Aceh Province, Indonesia, whereby an index case that met pre-determined socio-behavioral risk factors triggered follow-up testing at forest work sites (i.e. small mines and plantations) or other agreed venues, and amongst socially-networked groups of individuals reporting recent forest travel. We compared this approach to RACD amongst the household and neighbors of the index case. Between April 2017 and March 2018, 41 confirmed malaria cases in Aceh Jaya and Aceh Besar districts were screened for risk factors related to forest work. Amongst those with risk factors, 107 individuals were tested at work sites and other venues, and 3 infections confirmed by LAMP (2.8%); 38 individuals were identified and tested through their social networks, yielding 3 confirmed infections (7.9%); and 754 individuals were tested during household RACD, with only 2 confirmed positive (0.3%). These preliminary results suggest this "socio-behavioral" RACD approach is more effective in targeting the highest risk individuals in this setting. Cost-effectiveness data, entomological assessments conducted at high-risk work sites, and an additional six months of data will be included in the final analysis. RACD targeted based upon risk factors such as recent forest work can provide a method for Indonesia's national malaria program to treat the highest-risk populations and help achieve its elimination goals, and has the potential to be adapted to other malaria elimination contexts.

1846

MASS DRUG ADMINISTRATION COMBINED WITH INDOOR RESIDUAL SPRAYING FOR ACCELERATED REDUCTION OF MALARIA IN A HIGH TRANSMISSION SETTING IN NORTHEASTERN UGANDA: PRELIMINARY RESULTS

Dorothy C. Echodu[1], Kathryn Colborn[2], Humphrey Wanzirah[3], Ronald Mulebeke[3], Richard Elliott[4], Wycliff Odude[3], Fred Bukenya[3], Thomas Eganyu[3], Catherine Maiteki-Sebuguzi[5], Samuel Gonahasa[6], Mary Kyohere[6], Adoke Yeka[6]

[1]Pilgrim Africa, Seattle, WA, United States, [2]University of Colorado Denver, Denver, CO, United States, [3]Pilgrim Africa, Kampala, Uganda, [4]Micron School of Materials Science and Engineering, Boise, ID, United States, [5]Ugandan Ministry of Health, National Malaria Control Program Uganda, Kampala, Uganda, [6]Infectious Diseases Research Collaboration, Kampala, Uganda

Strategies to navigate from control to pre-elimination are not well defined in high transmission settings. An ongoing multi-year study in NE Uganda assesses the impact of four rounds of population based indoor residual spraying (IRS) with pirimiphos methyl, alone or in combination with mass drug administration (MDA) with dihydroartemisinin-piperaquine (DP), on malaria transmission, prevalence and incidence. Our hypothesis, supported by *Openmalaria* modeling, is that a temporary synchronous addition of DP to IRS compared to IRS alone in a high burden area will substantially reduce the initial burden of malaria. Three contiguous sub counties with a total population of ~50,000 people experience either: A: IRS + MDA + standard of care (SOC), B: IRS + SOC, or C: SOC, which includes continuous case management and a mass distribution of long-lasting insecticide treated nets (LLINs) in April 2017. Two rounds of IRS and MDA have been conducted, and two more are planned. Four surveys measuring prevalence by rapid diagnostic test (RDT), microscopy, and qPCR of approximately 2500 individuals, 200 households in each study area, were conducted in November 2016, one month before the interventions began, in June 2017, six months after the December 2016 round, in November 2017, three months after round 2, and most recently in March 2018. Baseline prevalence by rapid diagnostic test (RDT) was 49% (A), 49% (B) and 56% (C) in children <1 5. Prevalence after one round in this same population was 24% (A), 27% (B) and 61% (C). Differences between A and B were not significant. Prevalence after two rounds was 8% (A), 16% (B), and 46% (C), with A significantly reduced compared with B. Comparing this latter survey with the baseline, the relative risk of malaria positivity in A relative to B was .42 ($p<.001$), and essentially the same relative risk (OR .42, $p<.01$) was found for microscopy. Similar trends were seen in adults. Preliminary findings support the use of MDA in combination with IRS for dramatic reductions in malaria burden, which should ease subsequent control. This finding is important for policy makers in such settings as a means of acceleration towards elimination.

1847

AFGHANISTAN MOVING TOWARD MALARIA ELIMINATION

Ghulam Rahim Awab

Nangarhar University, Jalalabad, Afghanistan

Over the past 16 years, scaled-up key tools (ITN & ACT) contributed to malaria control in Afghanistan. This impact & strong commitment allows move from control to elimination. So, the species-specific & sub-national elimination efforts are based on: Malaria & its epidemic control tactics, technical & operative feasibility of malaria elimination, indigenous transmission break by 2020, strong political & financial commitment & synchronization with neighboring countries for elimination. >90%

PV causes morbidity mainly in east and requires radical cure with primaquine (PQ) to prevent relapse. Recent studies showed significant store of hypnozoites & that low dose (0.25mg/kg/d for 14 days) reduces relapse by 5-fold. G6PD testing is recommended for PQ deployment at scale. Based on *Annual Parasite Incidence (API)*, *Test Positivity Rates (TPR)*, malaria epidemiology, health systems development, the country is divided into three malaria Categories: 1- Transmission-reduction phase & on the path to elimination: Areas with *API* of ≥1 case /1000 population at risk /year; relatively high *TPRs* (≥9%); highly prevalent efficient malaria vector, nearness to endemic areas of Pakistan with uncontrolled bilateral migration; un-sufficient socio-economic & health systems development etc.) 2- Recommended for malaria elimination: Areas with *API* ≤1 case/1000 population at risk/year; relatively low *TPRs* (≤9%); absence of efficient malaria vectors; bordering eliminating countries, 3- Transmission free & recommended for re- transmission prevention: to start implementation of case based surveillance & case investigation from 2019. By 2020: 50% malaria incidence reduction nationally vs. 2016, Pf transmission interrupt & 0 indigenous malaria in Badghis, Farah, Ghor, Hirat, Nimrozl, Baghlan, Kunduz, Takhar & Badakhshan, the re-transmission prevented in eliminated areas. By 2022:70% malaria incidence reduction nationally vs.2016, Pf transmission interrupted & 0 incidence of indigenous malaria in Kabul, Logar, Parwan, Dykundi, Kapisa, Panjsher, Urozgan & all Provinces moved from Category 2 to 3; & re-transmission prevented in malaria eliminated areas.

1848

AN ORIGINAL FRAMEWORK FOR SETTING IMPROVED MALARIA STRATEGIC INTERVENTION PACKAGES AND RELATED TARGETS IN MAINLAND TANZANIA

Fabrizio Molteni[1], Ally Mohamed[2], Renata Mandike[2], Sigsbert Mkude[1], Manuela Runge[3], Sumaiyya Thawer[1]

[1]Swiss TPH, Dar es Salaam, United Republic of Tanzania, [2]NMCP, Dar es Salaam, United Republic of Tanzania, [3]Swiss TPH, Basel, Switzerland

Recent efforts in malaria control in Tanzania mainland has led to progressive changes in the epidemiological profile of malaria with prevalence in children aged 6-59 months declining from 18.1% in 2008 to 7.3% in 2017. As prevalence across the country continues to decline and heterogeneity in transmission increases, district level stratification of malaria burden becomes increasingly important for optimizing implementation of interventions to chart the transition from malaria control to elimination stage. In order to identify proper intervention packages, the country was stratified using data from DHIS2 and community based survey. This included school malaria parasitological survey (SMPS), annual parasite incidence, test positivity rate, confirmed malaria incidence and malaria prevalence in pregnant women. The SMPS was used as reference point to determine the cut offs for the other indicators. Four epidemiological strata were proposed; very low, low, moderate and high. The resulting stratification showed that 28 districts with 12% of the population were in the very low strata, 34 districts with 28% of the population in the low strata and 122 districts with 60% of the population residing in the moderate to high strata. Following stratification and selection of most appropriate intervention packages per strata, modelling was used in the strategic planning process to predict the expected impact on malaria prevalence and cost of deploying different interventions packages. This stratification approach with support from modelling provided an improved framework for mainland Tanzania to set differential targets towards elimination.

Large scale risk mapping of malaria has, until recently, been largely based on parasite rate (PR) data from cross-sectional surveys. Publicly available national household surveys make this a robust, population representative data source. These data are, however, of limited utility outside of sub-Saharan Africa where national malaria surveys are far less common. PR is also a limited metric in low transmission settings where the sample sizes needed to detect blood stage infections are untenably high. Serological surveys overcome this problem somewhat due to the long-lasting antigens and the ability to detect historical exposure. The geographic scope of such surveys is often limited, though, due to the higher cost of processing such results. In many malaria endemic settings, case reports may therefore be a more reliable measure of the transmission landscape. Digital health information system platforms have improved both the completeness and accuracy of routine surveillance data, and moreover have made these data more readily accessible beyond the point of the health facility or district alone. This data is temporally rich, but may lack the spatial granularity needed to generate high resolution risk maps. Joint modelling methods have been developed to allow PR, serology and routine surveillance case incidence data to be leveraged to generate fine scale spatio-temporal outputs informed by multiple complimentary data sources. Such methods have been illustrated in varying transmission settings such as Haiti and Mozambique. The resulting maps have been applied to inform risk stratification and other control and elimination planning efforts.

The development of an effective blood-stage malaria vaccine holds significant promise for reducing the morbidity and mortality associated with clinical malaria. The reticulocyte-binding protein homologue 5 (RH5) is the most promising blood-stage *P. falciparum* candidate antigen to date. It is essential for erythrocyte invasion, and has shown *in vivo* efficacy in non-human primates. Protection was strongly correlated with anti-RH5 serum IgG antibody concentration and *in vitro* functional growth inhibition activity (GIA). We have shown the recombinant protein RH5.1 delivered with GSK's adjuvant AS01B to be safe and immunogenic in

a dose-escalating Phase Ia study in healthy UK adults (NCT02927145, unpublished). Here we report on the promising immunogenicity of the fractional dose group from the Phase Ia trial, where 12 volunteers received 2x 50 µg of RH5.1/ AS01B 4 weeks apart, followed by a delayed 10 µg dose 6 months later. We then present data on vaccine efficacy, assessed using a blood-stage controlled human malaria infection (CHMI) model against both primary and secondary homologous *Plasmodium falciparum* 3D7 clone challenge. 30 healthy malaria-naïve UK volunteers were recruited into this CHMI study. 15 received 3x 10 µg doses of RH5.1/ AS01B (4 weeks apart) and then received an intravenous injection of parasitized red blood cells in parallel with 15 control volunteers. Impact of the vaccine on qPCR-derived parasite multiplication rate (PMR) was the primary efficacy endpoint. 9 of these vaccinees and 8 controls have since undergone a second homologous CHMI to assess durability of immunity, compared to a third group of 6 new malaria-naïve controls. Results of both the first and second *P. falciparum* blood-stage challenges will be presented.

1851

ANTIBODIES AGAINST PYMIGS, A NOVEL TRANSMISSION-BLOCKING VACCINE CANDIDATE, REDUCE THE MOTILITY OF MICROGAMETES

Mayumi Tachibana, Motomi Torii, Takafumi Tsuboi, Tomoko Ishino

Ehime University, Matsuyama, Japan

Malaria transmission-blocking vaccine aims to inhibit the development of malaria parasites in mosquitoes by antibodies targeting surface proteins of sexual stage parasites. We have previously identified PyMiGS, a protein expressed on the surface of microgametes of *Plasmodium yoelii (*Py) to elicit antibodies with potent transmission-blocking activity. In this study, we aimed to investigate the mode of action of anti-PyMiGS antibodies against parasite development. Activated male gametocytes in mosquito midguts first egress from the erythrocytes, followed by exflagellation soon after the blood meal. To mimic the *in vivo*environment, Py gametocytes were mixed with activation medium containing anti-PyMiGS antibodies or anti-GST (control) and subsequently processed for electron microscopy after 15 min incubation. We observed exflagellation in both anti-PyMiGS and control group. However, whereas most microgametes were released from the residual body of activated male gametocytes in the control group, a significantly reduced number of microgametes were released in the presence of anti-PyMiGS antibodies, with most left attached on the residual body. Moreover, anti-PyMiGS antibodies shortened the duration of the active movement of microgametes after the onset of exflagellation to a fifth of the control. Put together, these findings suggest that anti-PyMiGS antibodies bind to microgamete surface immediately after exflagellation, thereby reducing microgamete motility and inhibiting microgamete release from activated gametocytes.

[1]EpiVax, Inc., Providence, RI, United States, [2]Leidos LIfe Sciences, Frederick, MD, United States, [3]Jenner Institute, University of Oxford, Oxford, United Kingdom, [4]Malaria Vaccine Development Program, United States Agency for International Development (USAID), Washington, DC, United States

In silico epitope prediction and analysis tools EpiMatrix and ClustiMer were used to identify class I and class II epitopes providing broad HLA coverage in RH5, a highly conserved *Plasmodium falciparum* blood-stage antigen that has recently been assessed in a Phase I clinical trial with controlled human malaria infection (CHMI). In addition, sequence similarity to the human proteome regarding the potential for cross-reactive epitopes, which may induce regulatory T cell responses, was also analyzed using the JanusMatrix algorithm. In contrast to other well-studied *P. falciparum* antigens such as TRAP, CSP, and EBA-175, high levels of class I and class II T cell epitope content were found in RH5, including thirteen class II epitope clusters. Predicted epitopes were synthesized as peptides and validated in competition binding assays with soluble class I and class II HLA as well as in Interferon gamma ELISpot assays using PBMC from clinical trial vaccinees administered RH5.1, a full-length recombinant RH5 protein vaccine. Criteria for selection of high value vaccine candidate epitopes as well as data correlating T cell response with in silico and *in vitro* indicators of donor HLA-specific potential for inflammatory, regulatory or lack of response will be shown.

Malaria vaccine trials assess product safety, immunogenicity, and efficacy; these endpoints can be confounded by intercurrent illnesses that may be deemed adverse events or may mimic or aggravate clinical malaria episodes. Furthermore, concurrent illnesses, such as malaria or respiratory infections, can impair vaccine responses. Therefore, defining the prevalence of common diseases and their distribution in different socio-demographic stratifications is helpful to prepare a site for the evaluation of vaccine safety and efficacy. In preparation for malaria community transmission blocking vaccine trials, we initiated a study of Community Dynamics of Malaria Transmission and Mosquito Feeding in Bancoumana, Mali in February 2018. Bancoumana is a village located 60 km southwest of Bamako with a population of about 10,000 people, and malaria transmission is highly seasonal with low incidence during the dry season from approximately January through June. As part of this observational study, we assessed disease frequency at enrollment of all age groups. We enrolled 957 subjects who were screened, including clinical exam, baseline hematological parameters, and malaria parasite density, with diagnostic assays and assessments as appropriate for any ongoing illness.Out of all participants, 32.3% (309/957) presented with at least one clinical abnormality at enrollment. Respiratory infection were by far the most commonly reported disease [11.0% (105/957)], with highest frequency among children under 5 years old [26.1% (47/180)]. The second most common infection was uncomplicated malaria [2.8% (27/957)] followed by gastroenteritis [2.1% (20/957)], both again most commonly in children under five years old [3.9% (7/180); 5.0 % (9/180)]. No difference was observed between sexes regarding the distribution of reported diseases. Less than 25% of volunteers reported a hemoglobin value under 11.7 g/dl. Infectious diseases, which are known to modify human immunity, were prevalent at the Bancoumana clinical trial site but varied widely between age groups. These findings will be considered when designing vaccine trials at this site.

1854

DOES CHALLENGE ROUTE MATTER? AN INVESTIGATION INTO THE CHALLENGE MODEL ELEMENT IN MOUSE MALARIA PROTECTION STUDIES

Katherine L. Mallory, Kathryne D. Walker, Neeraja M. Punde, Christopher J. Mann, Sarah C. Smith, Tatyana Savranskya, Evelina Angov

Walter Reed Army Institute of Research, Silver Spring, MD, United States

While researchers have nominally identified numerous malaria vaccine candidates, many of these candidates have yet to be translated into successful products for human use. A significant hurdle to malaria vaccine development remains the improvement and adaptation of biological models to approximate the natural condition of human infection and disease. Animal models are routinely used as a means to investigate a vaccine candidate's immunological and protective potential, in particular the *Plasmodium berghei* infection in rodents. Methods of infection within the *P. berghei* model may include artificial injection or inoculation by infected mosquitoes. Each of these routes have their merits and pitfalls. For example, appeals of artificial injection are direct control of sporozoite dosage and simplicity of delivery route. However, needle inoculation often bypasses relevant phases of natural infection while introducing other obstacles, e.g. viability. The natural infection route by mosquito is the most relevant option, but is labor intensive and introduces several uncontrollable factors, e.g. salivary gland sporozoite burden. To investigate how artificial and natural challenges compare in murine studies, our lab performed a series of experiments to assess the *P. berghei* murine model for infectivity and protection using two homologous antigens, PbCSP and PbCelTOS. Our findings suggest that challenge route can have an impact on antigen-specific protection interpretations and vaccine efficacy determinations. PbCSP vaccination conferred increased protection from malaria infection by mosquito bite when compared to intravenous, suggesting that bypassing the skin-stage reduced sensitivity to antibody-mediated inhibition. We will define fine specificity of humoral immune responses in order to establish the role of antibodies in the protection models. Since the malaria scientific community relies on the use of rodent parasite challenges to predict clinical outcomes, investigating vaccine candidates using a range of challenge methods may improve understanding of the relationship between infection and vaccine-induced immunity.

INFORMING TARGET PRODUCT PROFILES FOR A SECOND-GENERATION CHILDHOOD MALARIA VACCINE: A MODELLING STUDY

Alexandra B. Hogan[1], Peter Winskill[1], Robert Verity[1], Jamie T. Griffin[2], Azra C. Ghani[1]

[1]Imperial College London, London, United Kingdom, [2]Queen Mary University, London, United Kingdom

Clinical trials of the RTS,S/AS01 vaccine for *P. falciparum* malaria have demonstrated a protective effect in young children and, beginning in 2018, the four-dose vaccine will be evaluated through a pilot implementation program in Ghana, Kenya and Malawi. Work is currently underway to optimise this vaccine. A recent phase 2a human challenge study indicated that varying the timing and dose amount of the fourth dose could further improve vaccine efficacy. In our study we used a dynamic modelling approach to inform target product profiles (TPPs) for a second-generation malaria vaccine for 5-17-month-old children, focussing on the specific characteristics of initial efficacy, duration of protection, dosing schedules and coverage. We also compared the RTS,S/AS01 phase 3 efficacy with an efficacy profile based on data from the phase 2a challenge study. In the first decade of delivery, we found that initial efficacy was more important than duration, due to the efficacy benefit occurring in younger ages. This effect was more pronounced in high transmission settings. However, the low initial efficacy and long duration schedule averted more cases across all ages if a longer time horizon was considered. The modified vaccine profile outperformed the RTS,S/AS01 phase 3 profile, although a profile with higher efficacy at the fourth dose, and a longer delay between doses three and four, conferred the most benefit overall. Our findings indicate that for an imperfect childhood malaria vaccine with suboptimal efficacy, it may be advantageous to prioritise initial efficacy over duration. We predict that next-generation vaccine with a modified dosage and schedule could outperform the current RTS,S/AS01, although fourth dose timing will affect the age group that derives the greatest benefit. This study provides insight into prioritising malaria vaccine characteristics and shows how distinct vaccine properties translate to public health outcomes.

EVALUATION OF PROTEIN CARRIERS FOR TRANSMISSION BLOCKING VACCINE ANTIGENS

Puthupparampil V. Scaria[1], Christopher G. Rowe[1], Beth B. Chen[1], Emma K. Barnafo[1], Emily Kelnhofer[1], Olga V. Muratova[1], Charles B. Anderson[1], Lynn E. Lambert[1], Kelly M. Rausch[1], Andrew Lees[2], David L. Narum[1], Patrick E. Duffy[1]

[1]Laboratory of Malaria, Immunology and Vaccinology/National Institute of Allergy and Infectious Diseases/National Institutes of Health, Rockville, MD, United States, [2]Fina Biosolutions, Rockville, MD, United States

Immunogenicity of poorly immunogenic antigens can be enhanced by chemical conjugation with carrier proteins or other particulate carriers. We have developed a conjugate nanoparticle system with EPA (Exoprotein A from *Pseudomonas aeruginosa*) as carrier for the delivery of malaria antigens. EPA conjugates of Transmission Blocking Vaccine (TBV) antigens, Pfs25 and Pfs230 are being evaluated currently in clinical studies. With the goal of augmenting the immunogenicity of the conjugates further, we are currently exploring other carriers for the delivery of these antigens. These include carriers such as Tetanus Toxoid and CRM_{197}, used in approved vaccines as well as two variants of these carriers, Tetanus Toxin heavy chain (rTThc) and EcoCRM™ (Fina Biosolutions), both expressed in E. coli. We conjugated Pfs25 to TT, CRM_{197}, rTThc and EcoCRM™ and characterized their physicochemical and immunological properties. Chemical conjugations were carried using thioether chemistry that is currently employed for EPA conjugates. Conjugates were analyzed for their molecular weight and antigen/carrier composition by SEC-MALS and amino acid analysis respectively. Mouse immunogenicity studies of Pfs25 conjugates showed strong immune response against Pfs25 with antibody titer similar to EPA-Pfs25 conjugate. Functional analysis of the immune sera by Standard Membrane Feeding assay demonstrated high inhibition of oocyst formation in the infected mosquitos. Antibody titer and functional activity of rTThc were equivalent to those of TT, despite their structural differences. Similarly, EcoCRM and CRM_{197} showed essentially identical immunogenicity and functional activity. In conclusion, all four carriers appear to be suitable for TBV antigen delivery.

1857

THE FIRST HUMAN MONOCLONAL ANTIBODY AGAINST THE SEXUAL STAGE *PLASMODIUM FALCIPARUM* ANTIGEN PFS230

Seattle, WA, United States, [5]Division of Immunology and the Children's Research Center, University Children's Hospital, University of Zürich, Zürich, Switzerland

Malaria transmission-blocking vaccines (TBVs) induce antibodies against proteins expressed by the parasite in the mosquito midgut and are an innovative approach to reduce parasite transmission and contribute to malaria elimination. Antibodies against Pfs230, a protein on the surface of *Plasmodium falciparum* gametes, can block parasite transmission, and Pfs230 vaccine candidates are currently in clinical trials. Antibody repertoire analyses, performed by B cell receptor (BCR) sequencing, have been employed to evaluate responses to other vaccines and to identify sequences of neutralizing antibodies. Here, we used a Pfs230 tetramer to sort Pfs230-specific single B cells (CD3-, CD14-, CD56-, CD19+, CD20+, CD27+, Pfs230+) generated after the fourth dose of Pfs230-EPA/Alhydrogel® in Malian adults. We sequenced both heavy and light antibody chains from these cells and identified paired BCR from nine vaccinees. The resulting sequences indicated expansion of clonotypes using IGHV1-69 (heavy chain) in 8 subjects and using IGKV4-1 (light chain) in 7 subjects. The IGHV1-69 clonotypes were characterized by high mutational rates with at least ten mutations per sequence in CDR1 and CDR2 regions, suggesting proliferation and selection in response to the vaccine. We developed and applied a method to rapidly generate Fab fragments by cell free expression; individual BCR of interest were identified based on repeated frequency on the plate, again suggesting clonal selection. Five paired heavy, and light chains were PCR amplified from selected wells. Using overlap extension PCR, all necessary elements for in vitro transcription and translation and either the CH1 or C-kappa-domain were added to both the 5' and 3' ends of the single cell VDJ. After in vitro transcription and translation, four out of five tested Fab fragments demonstrated binding through a colorimetric ELISA assay. To assess complement-dependent function, we generated a human IgG1 antibody in HEK cells using the same VDJ sequence. This new antibody, LMIV230-01, bound to Pfs230D1 recombinant protein in ELISA, to extract of female gametocytes in Western blot and to the surface of both female gametes and parasites in early developmental stages isolated from midguts three hours post-feeding; functional assays are ongoing and will be reported. These results will be fundamental for design and improvement of TBV strategies to induce potent antibody responses against mosquito stage parasites.

1858

INVESTIGATION OF TWO VACCINE-DELIVERY PLATFORMS TO ENHANCE IMMUNOGENICITY AND TRANSMISSION-BLOCKING ACTIVITY OF MALARIA VACCINE CANDIDATE PVS25

Arianna Marini[1], Daria Nikolaeva[2], Yuanyuan Li[1], Yu Zhou[1], Fergal Hill[3], Alexandre Le Vert[3], Jetsumon Sattabongkot[2], Sumi Biswas[1]

[1]University of Oxford, Oxford, United Kingdom, [2]Mahidol University, Bangkok, Thailand, [3]Osivax, Lyon, France

Over 2.8 billion people worldwide live at risk of *Plasmodium vivax* infection, in particular in the Americas and South-East Asia, where *P. vivax* account for >60% and >30% of all malaria cases respectively. An indispensable tool for malaria control and eradication are transmission-blocking malaria vaccines (TBV), with Pvs25 being one of the most studied vaccine candidate. Pvs25 is expressed on the parasite prior to fertilization and the expression peaks during the ookinete stage. Antibodies against this protein have demonstrated transmission-blocking activity in animals and humans. However, the high and long-lasting titres needed for functionality in humans are difficult to achieve. To overcome this problem, we investigated the use of two different vaccine delivery platforms: we genetically fused Pvs25 to IMX313, a chimeric version of the oligomerization domain from chicken complement inhibitor C4b-binding protein, and we used the SpyCatcher/SpyTag Plug-and-Display technology to display the antigen on the surface of virus-like particles. Preclinical investigation in mice showed that both platforms were suitable for eliciting high anti-Pvs25 antibody titres which were functional against field isolates of *P. vivax*. Data investigating the immune response and functional activity further to select one of the candidates to Phase 1 clinical trial will be presented.

1859

HETEROLOGOUS ADENOVIRAL IMMUNIZATIONS PROVIDE STERILIZING PROTECTION AGAINST *PLASMODIUM VIVAX* IN A SURROGATE MURINE MODEL

Jessica N. McCaffery[1], Jairo A. Fonseca[1], Luis E. Muñoz[1], Elena Kashentseva[2], Balwan Singh[3], Igor P. Dmitriev[2], David T. Curiel[2], Fidel P. Zavala[4], Alberto Moreno[1]

[1]Emory University, Atlanta, GA, United States, [2]Washington University School of Medicine, St. Louis, MO, United States, [3]Centers for Disease Control and Prevention, Atlanta, GA, United States, [4]Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States

Several heterologous prime-boost immunization regimens including DNA, MVA or adenoviral vectors have been reported to improve T cell responses to *Plasmodium* antigens as well as protective efficacy compared to homologous regimens. However, two immunizations with the same adenoviral vector are sufficient to induce anti-vector antibodies that reduce efficacy when compared to heterologous immunization regimens. Here we described the immunogenicity and efficacy of a heterologous adenoviral immunization regimen including the recombinant human adenovirus Ad5/3 and the simian adenovirus SAd36, tested in mice. These two vectors were used to deliver a chimeric multi-stage *P. vivax* protein that included T cell and B cell epitopes from two immunodominant antigens, the circumsporozoite protein (CSP) and the merozoite surface protein 1 (MSP1). Adenoviral immunizations were followed by two protein boosts with the corresponding chimeric proteins. Heterologous adenoviral regimens were compared with regimens consisting of only protein immunizations and naïve mice. Heterologous adenoviral regimens induced high titers of antibodies capable of recognizing the native structure of both *P. vivax* CSP and MSP1 by immunofluorescence, a balanced IgG1/IgG2a humoral response, and significantly improved IL-2 production by CD4 and CD8 T cells when the SAd36 was used for priming. When protection was assessed using a transgenic *P. berghei* expressing a *P. vivax* CSP repeat region as a surrogate model of protection, we observed greater than 99% reduction in parasite loads in the liver of immunized mice two days post experimental challenge compared to unvaccinated animals. Sterilizing protection was observed in 8/10 mice immunized with the Ad5/3-SAd36-protein regimen, and 9/10 mice immunized with the SAd36-Ad5/3-protein regimen, while only 50% of the protein immunized mice had sterilizing protection. Overall, our data demonstrate the ability of this vaccine candidate to induce protective and long-lasting humoral and cellular immune responses when delivered via heterologous adenoviral vectors.

1860

THE INFLUENCE OF SOCIO-ECONOMIC STATUS ON PERFORMANCE OF THE RTS,S MALARIA VACCINE AMONG CHILDREN WHO PARTICIPATED IN THE PRE-LICENSURE TRIAL

Stephaney Gyaase

Kintampo Health Research Centre, Kintampo, Ghana

Despite a substantial progress made in fighting malaria, it continuous to have a devastating impact on people's health and livelihoods. GlaxoSmithKline's (GSK) RTS,S malaria vaccine is currently the most advanced malaria vaccine in global development which has been found to provide a protective efficacy against clinical malaria among children (5-17 months). The objective of this analysis was to determine the influence of household (HH) socio economic status (SES) on the efficacy of the RTS,S malaria vaccine administered to children aged 5-17 months within Kintampo North Municipality and Kintampo South District of Ghana. The RTS,S malaria vaccine trial was a randomized, controlled, multicenter, participant- observer-blind phase III trial conducted at 11 different centers. Clinical malaria episode was defined as fever accompanied by a temperature greater or equal to 37.5^{o}C and *P. falciparium* asexual parasitemia greater than 5,000parasite/mm^{2}. HH assets such as television,

radio, etc were used in generating HH assets scores. Data of 1002 children ranging from 5 to 17 months who were followed up to 20 months was used for this analysis. A sum of 7,960 (approximately 11 episodes on average) distinct episodes of clinical malaria ranging from 1 to 30 were reported over the 20 months' period of follow-up. Within the RTS,S group, on an average 11 distinct episodes per child compared to 13 distinct episodes per child for children in the control group were reported. For each additional occurrence of clinical malaria, a child at baseline was found to be associated with 39% [0.72 (95% CI: 0.65 - 0.80)] increase in the recurrence risk for the control group compared to RTS,S group. A child within the RTS,S group with a low or medium socio-economic status has a decrease of 28% and 25% in the hazard of experiencing an episode of clinical malaria respectively. However, at a particular survival time, twice as many subjects from the high socio-economic class in the control group experience an episode of clinical malaria compared to the RTS,S group. In conclusion, a child's HH Socio economic status was found to have an influence on the effectiveness of RTS,S malaria vaccine.

1861

EXPLORATION OF VHH NANOBODIES AS STRUCTURAL MIMICS OF *PLASMODIUM VIVAX* INVASION EPITOPES AS A VACCINE

Kyle J. Riedmann, Lenore Carias, Christopher L. King

United States Veterans Affairs Research Service and Center for Global Health and Diseases, Case Western Reserve University, Cleveland, OH, United States

Development of successful subunit protein vaccines often fail because they may not precisely mimic the naturally occurring antigen responsible for protective immune responses, or are themselves weakly immunogenic. We propose Camelid single-domain (VHH) antibodies are capable of epitope mimicry by targeting the idiotope region of characterized functional human antibodies. Production of VHH antibodies in *E. coli* could have high yields without aggregation or loss of functionality. Anti-Id Ab vaccines have shown promising results against a number of tumor-associated antigens. Antibodies (humAbs) to rPvDBPII-SalI, which demonstrated blocking of rPvDBPII to erythrocytes, were generated from single-cell antigen-specific sorted B-cells from two Cambodian individuals with immunity to *P. vivax*. huMAbs were digested with papain to remove the Fc region. Protein G purified Fab fragments were coated onto 4HBX plates, and a commercial VHH phage display library was used to pan for anti-Id antibodies. Sequences of phage from round 4 provided determination of panning endpoint. Clones were produced as VHH-phage to test binding to target ligand. Competition ELISAs using the purified VHH antibodies and biotinylated rPvDBPII allowed for testing if the VHHs of block the rPvDBPII-huMAb interaction, and thus determine if the VHHs bind to the paratope. Sequencing results have revealed 5 distinct clonal groups for 2 different blocking humAbs panned against. Initial ELISA results using VHH-phage particles indicate positive binding to the primary antibodies. We await further results using purified VHH antibodies in a competition ELISAs. Phage display of VHH nanobodies offers a reproducible method of producing specific antibodies to antigens. Utilization of camelid VHH antibodies in vaccinations in mice and rabbits may reveal their value as a potential vaccine candidate for humans. The additional benefit of working with a camelid VHH library is our development of VHHs to malaria antigens offering advantages in imaging, flow cytometry, and ELISA assays that are not available with traditional antibodies.

"PRIME-TARGET" IMMUNIZATION WITH VIRAL VECTORS FOR ENHANCED EFFICACY OF LIVER-STAGE MALARIA VACCINES

Katie Ewer, Daniel Silman, Georgina Bowyer, Anita Gola, Duncan Bellamy, Catherine Mair, Mehreen Datoo, Ian Poulton, Rachel Roberts, Alison Lawrie, Alexandra Spencer, Adrian V. Hill

The Jenner Institute, University of Oxford, Oxford, United Kingdom

Induction of cell-mediated immunity targeting the liver-stage of malaria is a well-established strategy for eliciting sterile protection against human *Plasmodium falciparum* malaria. Intramuscular (im) administration of the liver-stage vaccine antigen ME-TRAP encoded within the viral vectors ChAd63 and MVA induces 21% sterile protection in a controlled human malaria model (CHMI) using *P. falciparum*-infected mosquitoes. Protection was associated with antigen-specific $CD8^+$ T cells expressing the cytokine IFNγ, measured in peripheral blood. Recently, tissue-resident T cells (Trm) have been identified as potential sentinels against invading pathogens in a variety of tissues and intravenous (iv) administration of irradiated, cryopreserved sporozoites has been shown to generate high-frequencies of liver Trm in non-human primates associated with sterile-protection against malaria. We hypothesised that increasing the frequency of TRAP-specific Trm in the liver by iv administration of viral vectors that are known to be liver-tropic would enhance sterile-protection against malaria. Building on positive pre-clinical data in mice, we proceeded to a small Phase I dose-escalation study assessing the safety of increasing doses of ChAd63 ME-TRAP iv. Immunisations were well-tolerated, with a safety profile similar to that observed following im administration of the same vaccine. Immunogenicity, measured by IFNγ ELISPOT using peripheral lymphocytes was associated with vaccine dose. We assessed the expression of two markers of human liver Trm (CD11a and CD69) and showed that the frequency of $CD8^+$ $IFN\gamma^+$ T cells was greater in participants immunised by the iv route than the im route. Further vaccinations are underway to include dose-escalation of MVA ME-TRAP and extended immunology for both vaccines will be presented to determine impact of iv vaccination on activation-induced markers, using the "AIMS assay". We will then progress to a Phase II trial assessing immunogenicity and efficacy of im prime-boost (ChAd63 and MVA ME-TRAP) followed by iv "targeting" with either vector to assess the improvement in efficacy against CHMI.

ACCOUNTING FOR EVERY LLIN: THE CASE OF LLIN ACCOUNTABILITY SYSTEM IN TANZANIA

Waziri Nyoni[1], David Dadi[1], Noela Kisoka[1], Jacqueline Madundo[1], Winfred Mwafongo[2], Ally Mohamed[2], George Greer[3], Naomi Kaspar[3], Ikupa Akim[4], Ato Selby[1], Eric Filemyr[1], Hannah Koenker[1], Matt Lynch[1]

[1]U.S. Agency for International Development VectorWorks Project, Johns Hopkins University Center for Communication Programs, Baltimore, MD, United States, [2]National Malaria Control Programme, Ministry of Health, Dar es Salaam, United Republic of Tanzania, [3]US President's Malaria Initiative, US Agency for International Development, Dar es Salaam, United Republic of Tanzania, [4]Swiss Tropical and Public Health Institute, Basel, Switzerland

Tanzania has adopted Reproductive and Child Health (RCH)-based distribution as a continuous distribution channel for long-lasting insecticide-treated nets (LLINs). The Tanzanian National Voucher Scheme was implemented from 2004-14 to deliver LLINs to pregnant women and infants at antenatal and immunization visits. Vouchers were given to pregnant women and could be redeemed for an LLIN at participating retail points. In 2014, the program was stopped due to fraudulent voucher redemptions. In 2016, a new distribution system for pregnant women and infants, the *Chandarua Kliniki (CK)* program, was launched. LLINs are delivered to recipients directly at health facilities without vouchers. The *CK* program has expanded to all 26 regions in Tanzania, delivering more than 3.4 million LLINs in 2016-2017, with about 3.4 million more to be

distributed each year. In order to account for every LLIN being distributed, a stringent accountability system was designed to reduce the possibility of fraud. DHIS2 indicators are integrated in a dashboard that automatically triangulates and compares the number of pregnant women that received ANC services and children who received measles vaccinations against those who received an LLIN. The dashboard generates monthly trends for review by programme planners. On a quarterly basis, the system also compares service information with commodity information, such as stock on hand from the electronic Logistics Management Information System (eLMIS). Information from the two systems is visualized in a dashboard that summarizes individual health facility performance and produces an accountability report that shows variances. The district malaria coordinators use the report to follow up with specific facilities on reported variances before they sign off and file their report. At the end of each quarter, the system produces a quarterly accountability report, which is reviewed by the council health management team. This presentation will report on the operational issues encountered during the implementation process and how the *CK* system has improved targeted supervision and monitoring of RCH-based LLIN distribution.

1864

LONG LASTING INSECTICIDAL BED NETS OWNERSHIP, ACCESS AND USE IN A HIGH MALARIA TRANSMISSION SETTING BEFORE AND AFTER A MASS DISTRIBUTION CAMPAIGN IN UGANDA

Humphrey Wanzira[1], Thomas Eganyu[1], Ronald Mulebeke[1], Fred Bukenya[1], Dorothy Echodu[1], Yeka Adoke[2]

[1]Pilgrim Africa, Kampala, Uganda, [2]Makerere University School of Public Health, Kampala, Uganda, Kampala, Uganda

Uganda conducted a second mass LLIN distribution campaign and Katakwi district recently received LLINs as part of this activity. This study was conducted to measure the success of the campaign in this setting, an area of high transmission, with the objectives to estimate LLIN ownership, access and use pre and post campaign implementation. Two identical cross sectional surveys, based on the Malaria Indicator Survey methodology, were conducted in three sub-counties in this district (Kapujan, Magoro and Toroma), six months apart, one before and another after the mass distribution campaign. Data on three main LLIN indicators including; household LLIN ownership, population with access to an LLIN and use were collected using a household and a women's questionnaire identical to the Malaria Indicator Survey. A total of 601 and 607 households were randomly selected in survey one and two respectively. At baseline, 60.57% (56.53-64.50) of households owned at least one net for every two persons who stayed in the household the night before the survey which significantly increased to 70.35% (66.54-73.96) after the campaign (p= 0.001). Similarly, the percentage of the household population with access to an LLIN significantly increased from 84.76% (82.99-86.52) to 91.57% (90.33-92.81), p= 0.001 and the percentage of household population that slept under an LLIN the night before the survey also significantly increased from 56.85% (55.06-58.82) to 81.72% (76.75-83.21), p= 0.001. The LLIN mass campaign successfully achieved the national target of over eighty-five percent of the population with access to an LLIN in this setting, however, universal household coverage and use were fourteen and three percent points less than the national target respectively. This is useful for malaria programs to consider during the planning of future campaigns by tailoring efforts around deficient areas like mechanisms to increase universal coverage and behavior change communication.

LESSONS LEARNED FROM MONITORING INDOOR RESIDUAL SPRAYING (IRS) IN ATACORA DISTRICT, BENIN, 2011-2016

R. Aïkpon[1], G. Padonou[2], F. Dagnon[3], R. Ossé[2], M. Kouletio[4], M. C. Akogbeto[1]

[1]Centre de Recherche Entomologique de Cotonou, Cotonou, Benin, [2]Université Nationale du Bénin, Cotonou, Benin, [3]U.S. President's Malaria Initiative, US Agency for International Development, Cotonou, Benin, [4]U.S. President's Malaria Initiative, U.S. Agency for International Development, Cotonou, Benin

Indoor residual spraying (IRS), an integral component of Benin's national malaria control plan, was performed in May/June in areas of northern Benin during 2011–2016. During this time period, we performed human landing catches (HLCs) to collect mosquitoes from eight homes in two villages where IRS occurred and in two villages where IRS did not occur to assess malaria vector biting and infectivity rates and to calculate entomological inoculation rates (EIR). HLCs occurred every one to three months between June 2011 and October 2016 (five months in 2011, ten in 2012, six in 2013, six in 2014, eight in 2015, and four in 2016). We assessed IRS insecticide performance by measuring the residual activity of bendiocarb and pirimiphos methyl (EC/CS) on IRS-treated walls using the WHO cone bioassay. We also monitored vector insecticide resistance in IRS villages by performing WHO insecticide susceptibility tests. During periods of high transmission (rainy season) in 2011–2016, significant decreases in malaria transmission were observed in IRS villages compared to controls: peak EIR/person/night in IRS villages was 0.04 compared to 1.5 in controls in 2011 (97% less); 0.3 v 1.6 in 2012 (84% less), 0.1 compared to 3.1 in 2013 (96% less), 0.1 compared to 0.4 in 2014 (75% less), 0.1 compared to 1.4 in 2015 (91% less), and 0.2 compared to 1.6 in 2016 (88% less). The residual activity of IRS insecticides on treated walls did not exceed four months. While large decreases in EIRs occurred in IRS villages, residual malaria transmission continued to occur with peak EIR/person/month of 11.3 in 2011, 10.8 in 2012, 8.2 in 2013, 2.8 in 2014, 5.6 in 2015, and 5.7 in 2016. *An. gambiae* sensitivity to bendiocarb was lost over time: mortality decreased from 97.8% in 2011 to 70% in 2016. Sensitivity to pirimiphos methyl remained at 100%. Our data suggests that IRS was effective in reducing malaria transmission through reducing EIRs, but that residual malaria transmission continued to occur. The low residual activity of the IRS insecticide may be resolved with new generation insecticide products and synergists.

1866

AGE GRADING MALARIA TRANSMITTING MOSQUITOES USING FEED FORWARD ARTIFICIAL NEURAL NETWORKS

Masabho P. Milali

Marquette University, Milwaukee, WI, United States

Near infrared spectrometry (NIRS) is currently complementing techniques to age-grade mosquitoes. NIRS can classify lab-reared and semi-field raised mosquitoes into < or ≥ 7 days old age groups with an average accuracy of 80%. This accuracy was achieved by training a regression model using partial least squares (PLS) and interpreting the model as a binary classifier. In this study, we explore whether using an artificial neural network (ANN) analysis instead of PLS improves the current accuracy of NIRS models on age-grading malaria transmitting mosquitoes. We also determined if directly training of a binary classifier instead of training a regression model and interpreting it as a binary classifier improves the accuracy. A total of 786 spectra of laboratory reared *Anopheles gambiae* were used and pre-processed according to previously published protocols. Based on ten replicates, we find that training both regression and binary classification age models using ANN yields models with higher estimation accuracies than when the same models are trained using PLS. While ANN regression model scored root mean squared error (RMSE) and mean absolute percentage error (MAPE) of 1.6 (+/- 0.2) and 30.6 (+/- 4.7), respectively, PLS regression model scored 3.7 (+/- 0.2) and 67.6 (+/- 6),

respectively. When we interpreted regression models as binary classifiers, the accuracy, specificity and sensitivity of ANN regression model were 93.7 (+/- 1.0)%, 95.6 (+/- 1.8)%, and 92.5 (+/- 1.6)%, respectively while PLS regression model scored 83.9 (+/- 2.3)%, 75.8 (+/- 5.2)% and 89 (+/- 2.1)%, respectively. We also find that a directly trained binary classifier yields higher age estimation accuracy than a regression model interpreted as a binary classifier. While a directly trained ANN binary classifier scored an accuracy, sensitivity and specificity of 99.4 (+/- 1.0)%, 99.3 (+/- 1.3)% and 99.5 (+/- 0.7)%, a directly trained PLS binary classifier scored 93.6 (+/- 1.2)%, 94.4 (+/- 1.6)% and 92.4 (+/- 1.9)%, respectively. These results suggest the use of ANN models for age grading *An. gambiae*, however validation on larger data set and on other species is required.

1867

RESPONSE OF TWO POPULATIONS OF *ANOPHELES GAMBIAE* S.L. EXPOSED TO DELTAMETHRIN, PERMETHRIN, AND PERMETHRIN WITH PBO AND DEF SYNERGISTS USING WHO AND CDC BIOASSAYS

H. Sagbohan[1], C. Kpanou[1], F. Dagnon[2], M. C. Akogbeto[1]

[1]Centre de Recherche Entomologique de Cotonou, Cotonou, Benin, [2]U.S. President's Malaria Initiative, U.S. Agency for International Development, Cotonou, Benin

Benin faces widespread insecticide resistance in malaria vectors. We used WHO and CDC bioassays to quantify resistance to deltamethrin, permethrin, and permethrin with piperonyl butoxide (PBO) and S,S,S-tributyl phosphorotrithioate (DEF) synergists, which inhibit oxidase and esterase activities, respectively, with 2-5 day-old *Anopheles gambiae* from two cities in northern and southern Benin. We used PCR for species identification and genotyped *Kdr L1014F* and G119S *Ace-1R* mutations. Of 278 *An. gambiae s.l* collected, 99.3% (n=276) were *An. coluzzii*, 90.0% (n=270) had the *Kdr* L1014F gene mutation, and 3.0% (n=10) had the G119S *Ace-1R* mutation. Using CDC bioassays, 16.1% of southern and 12.3% of northern mosquitoes survived after exposure to diagnostic doses of permethrin (standardized dose corresponding to 99.9% mortality of susceptible mosquitoes as established by WHO). After exposure to doses of permethrin that were 2X higher, 14.1% of southern and 8.4% of northern mosquitoes survived; after exposure to permethrin doses 5X higher, 0% of southern and 1.2% of northern mosquitoes survived. When exposed to diagnostic doses of deltamethrin, 12.2% of southern and 13.9% of northern mosquitoes survived. At deltamethrin doses 2X higher, 3.2% of southern and 4% of northern mosquitoes survived; no mosquitoes survived after exposure to doses 5X higher. Using WHO bioassays, 23.9% of southern mosquitoes and 22.0% of northern mosquitoes survived after exposure to diagnostic doses of permethrin. When permethrin was combined with PBO, survival decreased to 12.7% and 5.1% among southern and northern mosquitoes, respectively. When diagnostic doses of permethrin were combined with DEF, southern mosquito survival remained similar at 23.4% but decreased to 11.6% among northern mosquitoes. High resistance to insecticides was identified in northern and southern sites in Benin, likely caused by several mechanisms including *Kdr L1014F* and G119S *Ace-1R* mutations and over-expression of oxidases and esterases. However, when diagnostic doses of permethrin were combined with PBO and DEF, resistance decreased by 46–77% in some mosquito populations.

1868

PREDICTIVE MODELING FOR ASSESSING BIO-EFFICACY OF LONG LASTING INSECTICIDE NETS IN GUATEMALA USING SEGMENTED REGRESSION

Henok Woldu[1], Maria Eugenia Castellanos[1], Soledad Rodas[2], Steve Smith[3], Audrey Lenhart[3], Norma Padilla[2]

[1]Department of Epidemiology and Biostatistics, College of Public Health, University of Georgia, Athens, GA, United States, [2]Center for Health Studies, Universidad del Valle de Guatemala, Guatemala, Guatemala, [3]United States Centers for Diseases Control and Prevention, Atlanta, GA, United States

Use of long lasting insecticide nets (LLINs) has had a significant impact on personal protection and in reducing malaria transmission. Therefore, nowadays, LLINs are one of the cornerstones of malaria control. The WHO cone bioassay is the recommended methodology for determining the bio-efficacy of a LLIN. However, logistically simpler alternatives are welcomed. The bromine x-ray fluorescence (XRF) has been used to measure insecticide content and has proven to be a feasible alternative to high liquid performance chromatography (HPLC). This study was conducted to assess if the results from the XRF analysis could serve as a predictor to estimate the bio-efficacy results in LLINs. Our data was obtained from a study conducted in La Gomera, Guatemala in which 174 LLINs were collected and evaluated by both techniques during three time-points (2013, 2014 and 2015). For this purpose, we developed a model using piecewise (segmented) regression. Piecewise regression is used when there are clearly two or more linear relationships in the data with a sudden, sharp change in direction. Exploratory analysis of our data showed the relationship between our response variable-proportion of mortality of mosquitoes/24 hours by the cone bioassay- and the main exposure variable-mg deltamethrin by the XRF analysis-, can be explained as two separate linear relationships where the change in the direction of the relationship occurs around the cutoff of 25 mg of deltamethrin. To develop our predictive model, we used cross validation. We trained our model using 80% of the data and validated it with the remaining 20%. This process was repeated 100 times. To assess the accuracy of the fitted model, a confusion matrix was built to calculate the proportion of correct classification. The average accuracy our model was estimated to be 89.94 %, indicating that approximately 90% of the time we can estimate the bio-efficacy of LLIN correctly based on two predictors: the results from the XRF analysis and the age of the LLINs.

1869

IS BIOKO GETTING THE HANG OF IT? EVALUATION OF A UNIVERSAL LONG-LASTING INSECTICIDAL NET (LLIN) DOOR-TO-DOOR DISTRIBUTION AND HANG-UP CAMPAIGN IN EQUATORIAL GUINEA

Jordan Smith[1], Jose Osa Osa Nfumu[1], Jeremias Nzamio[1], Lucas Ondo Nze[1], Liberato Motobe[1], Olivier Tresor Donfack[1], Wonder Philip Phiri[1], Carlos Cortes Falla[1], Luis Tam[2], Christopher Schwabe[2], Guillermo Garcia[2]

[1]Medical Care Development International, Malabo, Equatorial Guinea, [2]Medical Care Development International, Silver Spring, MD, United States

Despite the known effectiveness of long-lasting insecticidal nets (LLINs) in providing protection against malaria, maintaining universal coverage and use continues to be a challenge. To maintain universal coverage, the Bioko Island Malaria Control Project (BIMCP) has applied a combination of mass free distributions and continuous distributions through multiple channels. Strategies such as door-to-door visits and hang-up activities are being integrated into mass distribution campaigns to encourage higher LLIN usage. Mass door-to-door distribution campaigns include a pre-registration of persons and sleeping spaces, sensitization, and hanging of LLIN by community volunteers to encourage high and sustained use. From February to July 2018, the BIMCP is leading a mass LLIN distribution campaign on Bioko Island with the goal of achieving universal coverage. Data on the number of sleeping spaces, LLINs previously owned, LLINs received, and LLINs hung are recorded in an Open Data Kit (ODK) based Campaign Information Management System (CIMS) that facilitates longitudinal analyses of household-level interventions. A cross-sectional malaria indicator survey (MIS) will be conducted two to five months after the mass distribution campaign to collect information on individual parasitemia, LLIN survivorship, and use. This study will explore community, household, and individual level associations between parasitemia and factors related to LLIN survivorship and use among households in which LLINs were hung and those in which LLINs were not hung. The results

will add to the evidence base for decision-making on future distribution strategies that seek to incorporate novel approaches to encourage higher LLIN usage.

1870

RAPID REDUCTION OF MALARIA TRANSMISSION AFTER INTRODUCING A THIRD GENERATION INDOOR RESIDUAL SPRAYING PRODUCT IN PREVIOUSLY UNSPRAYED DISTRICTS OF MOPTI REGION, MALI IN 2017

Joseph Wagman[1], Christelle Gogue[1], Kenzie Tynuv[1], Jules Mihigo[2], Seydou Fomba[3], Elie Bankineza[4], Mamadou Bah[4], Diadier Diallo[5], Andrew Saibu[6], Jason Richardson[7], Laurence Slutsker[1], Molly Robertson[1]

[1]PATH, Washington, DC, United States, [2]U.S. Agency for International Development, US President's Malaria Initiative, Bamako, Mali, [3]Programme National de Lutte contre le Paludisme, Ministère de la Sante, Bamako, Mali, [4]PMI AIRS Project, Abt Associates, Bamako, Mali, [5]MEASURE Evaluation, Bamako, Mali, [6]NgenIRS Project, Abt Associates, Accra, Ghana, [7]NgenIRS Project, IVCC, Washington, DC, United States

Mali's national malaria control program (NMCP), working with the US President's Malaria Initiative (PMI) Africa Indoor Residual Spraying program, has had success decreasing malaria transmission using 3rd generation IRS (3GIRS) products in areas of pyrethroid resistance, primarily in Ségou and Koulikoro regions. In, 2015 national survey data showed that Mopti region had the highest under 5-year-old (u5) malaria prevalence at 53.4% - nearly twice the national average - despite having high access to long-lasting insecticidal nets (LLINs) and seasonal malaria chemoprevention (SMC). Migrations of displaced people to Mopti Region from Northern Mali, where malaria transmission is substantially lower and acquired immunity is thought to be low, has also complicated the landscape in Mopti. Accordingly, in 2016 NMCP, PMI, and other stakeholders shifted IRS activities from Ségou to Mopti. Here, we present observational analyses of this switch using routine malaria indicators. Health facility-level analysis of DHIS2 data showed a decline in confirmed u5 malaria cases following IRS: in the four months after spraying, health facilities in communities receiving IRS with pirimiphos methyl in addition to new LLINs and SMC reported 254 (37%) fewer confirmed cases per 10,000 children-months at risk compared to those receiving only new LLINs and SMC. Comparing changes in peak u5 incidence from 2016 to 2017, facilities receiving no IRS reported 20% (CI_{95} = 32% - 8%) fewer cases, while facilities receiving IRS in 2017 reported 51% (CI_{95} = 59% - 43%) fewer cases, a 31% greater decrease compared to non-IRS facilities. Entomological surveillance data also showed that reduced malaria incidence corresponded to reductions in indoor *An. gambiae* s.l. densities. Forthcoming analyses will also explore trends in malaria burden in Ségou after IRS was suspended. IRS provided significant added protection from malaria to a package that included a concurrent universal LLIN distribution campaign and high SMC coverage. These observations add to the growing evidence that 3GIRS can be a wise public health investment.

1871

FACTORS ASSOCIATED WITH REFUSAL AND RELUCTANCE TO INDOOR RESIDUAL SPRAYING ON BIOKO ISLAND, EQUATORIAL GUINEA

Olivier Tresor Donfack[1], Charity Okoro Eribo[1], Lucas Ondo Nze[1], Liberato Motobe[1], Jordan Smith[1], Wonder Philip Phiri[1], Carlos Cortes Falla[1], Luis Tam[2], Christopher Schwabe[2], Guillermo Garcia[2]

[1]Medical Care Development International, Malabo, Equatorial Guinea, [2]Medical Care Development International, Silver Spring, MD, United States

Indoor Residual Spraying (IRS) has proven to be a robust control measure against malaria, and until 2015 it was the primary vector control strategy under the Bioko Island Malaria Control Project (BIMCP). However, its effectiveness strongly depends on public acceptance by the targeted populations. This study aims to describe IRS acceptance and to investigate factors related to refusal and reluctance amongst the populations of Bioko Island. A secondary data analysis of the 2017 annual Malaria Indicator (MIS) survey; which collected valid data on 4,835 random households, selected from every community on the Island was conducted. The multinomial logistic regression was used to assess factors associated with IRS refusal and reluctance. 39% percent of households were reported to have been sprayed (not all communities are targeted for spraying). When respondents were asked if they will like their houses to be sprayed during the next IRS round, 81.1% accepted, while 11.1% refused and 7.8% were reluctant (don't know). The reasons mostly evoked for refusals were "IRS causes ill effects" (50%) and "IRS is disruptive or annoying" (25%). Respondents belonging to the middle and high wealth categories were more likely to refuse or to be reluctant to IRS; those living in households with heads having post-secondary educations were more likely to refuse IRS, and those who were not sure if their households were sprayed in the past were more likely to be reluctant to IRS. However, respondents living in the districts of Baney, Luba, and Riaba were less likely to refuse or to be reluctant to IRS when compared to Malabo. Individuals living in households that have been sprayed in the past were less likely to refuse or to be reluctant to IRS, and those previously exposed to malaria sensitization messages were less likely to be reluctant to IRS. Refusal and reluctance to IRS is almost 20% in households on Bioko Island, and are associated with socioeconomic, geographic, and educational factors. There is a need to improve malaria sensitization strategies, targeting every social class to increase IRS uptake.

1872

FOLLOW-UP OF LLIN'S SOON AFTER A MASS DISTRIBUTION CAMPAIGN IN TWO URBAN DISTRICTS IN MALABO, EQUATORIAL GUINEA

Teresa Ayingono Ondo Mfumu[1], Olivier Tresor Donfack[1], Jordan Smith[1], Wonder Philip Phiri[1], Carlos Cortes Falla[1], Guillermo Garcia[2]

[1]Medical Care Development International, Malabo, Equatorial Guinea, [2]Medical Care Development International, Silver Spring, MD, United States

The Bioko Island Malaria Control Project (BIMCP) uses bed nets as the primary vector control strategy on Bioko Island. As recommended by WHO, every three years the BIMCP, in partnership with the National Malaria Control Program (NMCP) of Equatorial Guinea, conducts mass distribution campaigns of long-lasting insecticide treated bed nets (LLINs) on Bioko Island. As well as distributes LLINS through routine keep-up campaigns in primary schools, high-risk communities, and Antenatal Care (ANC) clinics. However, results from annual malaria indicator surveys (MIS) have been highlighting the inadequate use of bed nets. Field workers providing anecdotal evidence suggest that the population has complained about the odor, the color, and adverse effects related to the nets (itchiness) in previous campaigns. To assess bed nets utilization and apprehension prior to the annual MIS and immediately post-distribution, the BIMCP will conduct a representative household survey in 2 urban districts of Malabo on Bioko Island in April 2018. Communities within the urban districts were selected by probability proportional to sizes and households were randomly selected in each community. The survey questions will focus on LLINs utilization and apprehension, reasons for not using LLINs, educational messages heard about LLINs, and the sources of the messages. This information will contribute to a better understanding of the needs of the population regarding LLINs and will improve communication and sensitization strategies concerning LLINs, with the goal of increasing utilization on Bioko Island.

1873

COMMUNITY ENGAGEMENT AND THE USE OF HOUSEHOLD MAPPING TO TARGET SENSITIZATION AND IMPROVE IRS COVERAGE ON BIOKO ISLAND

Lucas Ondo Nze[1], Olivier Tresor Donfack[1], Liberato Motobe[1], Jordan Smith[1], Godwin Fuseini[1], Wonder Philip Phiri[1], Megan Perry[2], Carlos Cortes Falla[1], Guillermo Garcia[2]

[1]Medical Care Development International, Malabo, Equatorial Guinea, [2]Medical Care Development International, Silver Spring, MD, United States

Since its inception in 2004, the Bioko Island Malaria Control Project (BIMCP) has relied on Island-wide IRS as one of the major malaria vector control strategies. Since 2015, the strategy has focused on targeting high-risk communities for IRS. Communities are selected by stratification based on high prevalence of malaria. However, not only does IRS coverage depends on public acceptance, but it is also highly dependent on the veracity and the accuracy of the data. It is challenging to accurately monitor IRS field operations, refusals in the population, and perform quality control on IRS activities. To reduce these challenges, the BIMCP began using spatial data to improve intervention coverage and collaborating with community leaders to support and strengthen IRS sensitization across the Island. In 2014, the Island was mapped into official government recognized communities and divided into grid sectors. Each household was then enumerated and assigned a unique identifier, which was placed on a sticker on the front door. A Campaign Information Management System (CIMS) was developed to track interventions at the household level on a longitudinal basis. IRS field data were entered directly into the CIMS tablet application and uploaded to a cloud server, enabling multiple household interventions spanning multiple years to be linked by a common unique identifier. Before mapping was introduced, IRS coverages were reportedly very high (above 90%). After mapping was introduced and data entry standardized, IRS coverage dropped to 57% during round 19 in 2014 and subsequently to 41% during round 20 the same year. After the engagement of the Ministry of Interior of Equatorial Guinea, in charge of community leaders, the support provided by these community leaders during mobilization and sensitization activities, increased IRS coverage to 81%, 71% and 82% in 2015, 2016 and 2017 respectively. The use of the CIMS, the mapping of households to systematically track IRS activities and data, led to targeted mobilization and sensitization through community leaders in identified high refusal areas for IRS, resulting in increased coverage.

1874

UTILIZING A CAMPAIGN INFORMATION MANAGEMENT SYSTEM AND HIGH PERFORMANCE LIQUID CHROMATOGRAPHY FOR IMPROVED QUALITY CONTROL OF INDOOR RESIDUAL SPRAYING WITH ACTELLIC 300 CS ORGANOPHOSPHATE INSECTICIDE ON BIOKO ISLAND OF EQUATORIAL GUINEA

Raul Nguema Ncogo[1], Godwin Fuseini[2], Hanafy Ismail[3], Wonder Philip Phiri[2], Liberato Motobe[2], Carlos Cortes Falla[2], Guillermo Garcia[2], Mark J. Paine[3]

[1]Ministry of Health and Social Welfare, Malabo, Equatorial Guinea, [2]Medical Care Development International, Malabo, Equatorial Guinea, [3]Liverpool School of Tropical Medicine, Liverpool, United Kingdom

Quality control of Indoor Residual Spraying (IRS) is necessary to ensure spray operators do not falsify spray records and that they deposit the recommended lethal dose of insecticides on spray walls. Insecticide Quantification Kits (IQK) for in-field quality control of IRS currently detects only concentrations of alpha-cyano pyrethroids and carbamates. IQK kits for in-field quality control with organophosphates are not yet developed though IRS programs are increasingly using organophosphates due to insecticide resistance to pyrethroids and DDT. This study examined the use of an advanced campaign information management system (CIMS) and high performance liquid chromatography (HPLC) for IRS quality control with an organophosphate insecticide. The Bioko Island Malaria Control Project (BIMCP) currently uses Actellic 300CS organophosphate insecticide with pirimiphos methyl as the active ingredient. A total of 17,600 households were sprayed in 2017 using 63 spray operators. The BIMCP instituted a quality control procedure to test houses randomly selected from the CIMS that maps and captures data in real time for houses reportedly sprayed each day. Insecticide samples were tape-lifted from structures reported sprayed and analyzed using HPLC. Spray operators were monitored in 2017 and 2018. During the 2017 monitoring, all the selected houses monitored had the insecticides deposits as detected by HPLC. However, 11.1% of the spray operators deposited less amount of the insecticide (<1.0g a.i./m²) on the wall, 54.0% deposited the target dose of 1.0g a.i./m² and 34.9% deposited over-dose >1.0 g a.i./m²). These results were compared with the 2018 monitoring results. The ability to randomly select, locate, and test houses sprayed reportedly within a week via HPLC has markedly improved the quality of IRS on Bioko Island, virtually eliminating falsification, and enabling the project to better evaluate its performance. The results obtained will also form the basis for developing new tool kits for in-field monitoring of organophosphates insecticides.

1875

OBSERVATIONAL ANALYSIS OF THE IMPACT OF THE REINTRODUCTION OF IRS IN DISTRICTS OF THE NORTHERN AND UPPER EAST REGIONS OF GHANA IN 2017

Christelle Gogue[1], Joseph Wagman[1], Kenzie Tynuv[1], Andrew Saibu[2], Keziah Malm[3], Wahjib Mohamed[3], Samuel Asiedu[3], Anthony Ofosu[4], Welbeck Akplu[4], Kwame Bimpeh[4], Jason Richardson[5], Molly Robertson[1]

[1]PATH, Washington, DC, United States, [2]Abt Associates, NgenIRS Project, Accra, Ghana, [3]National Malaria Control Program, Accra, Ghana, [4]Ghana Health Service, Accra, Ghana, [5]IVCC, Washington, DC, United States

Since 2008, Ghana has been implementing IRS as a key malaria control intervention in the northern savannah, including districts in Upper West, Upper East and Northern regions. The country has seen a steady decline in malaria prevalence since 2011. In 2011, the Northern and Upper East regions had a parasite prevalence in children under 5 of 48% and 44% to 39% and 25% by 2016. Organophosphate-based IRS was however suspended in Upper East in 2015 after two years of continuous implementation, but reintroduced in 2017 to three districts, Builsa North, Builsa South and Kassena Nakana West. Similarly, in 2017 IRS was re-introduced in two districts in Northern Region, Gushiegu and Karaga; both last sprayed in 2012 with a pyrethroid. The reintroduction in 2017 of IRS operations using an encapsulated organophosphate, pirimiphos-methyl in these districts offered an opportunity for an observational study of the impact of this new product. Routine epidemiological data from the national District Health Information Management System II were analyzed to calculate monthly malaria RDT-positive incidence rates at the health facility level. Changes from 2016 to 2017 in incidence rates in new IRS districts were compared to changes in incidence at health facilities without IRS in the same region to provide an estimate of intervention impact. Preliminary analysis of health facility-level data in the Upper East region in 2017 showed that there was an increase in malaria incidence in both IRS and non-IRS districts in the three months immediately after the spray campaign; however, IRS districts had approximately 155 fewer cases per 10,000 person-months of observation compared to non-IRS districts. IRS districts also showed lower rapid diagnostic test positivity rates (TPR) in the same months, with an average TPR 16% lower than in non-IRS districts. These analyses highlight the positive contribution of IRS in mitigating an overall increase in malaria cases in the north of Ghana. Routine surveillance data were useful to assess the impact of vector control interventions in operational settings and support evidence generation for IRS strategy decision-making.

1876

TESTING THE DURABILITY AND PERFORMANCE OF PERMANET 2.0 LONG-LASTING INSECTICIDE NETS AFTER THREE YEARS OF USE IN GUATEMALA

Maria E. Castellanos[1], Jose G. Juarez[2], Soledad Rodas[2], Lucrecia Vizcaino[3], Zoraida Morales[4], Jody Vanden[3], Steve Smith[3], Audrey Lenhart[3], Norma Padilla[2]

[1]College of Public Health University of Georgia, Athens, GA, United States, [2]Center for Health Studies, Universidad del Valle de Guatemala, Guatemala, Guatemala, [3]United States Centers for Disease Control and Prevention, Atlanta, GA, United States, [4]Medical Entomology Section, Vector-borne Diseases Program, Ministry of Public Health and Social Assistance, Guatemala, Guatemala

Long-lasting insecticidal nets (LLINs) are a standard measure for the prevention and control of malaria, impacting personal protection and in reducing malaria transmission. In Guatemala, since 2000, an estimated of 2million bednets have been distributed in the highest risk malaria-endemic areas, and to date constitute the main vector control measure in the country. However, there has not been a planned evaluation to determine the timely replacement of LLINs whose effectiveness becomes diminished by routine use. To determine survivorship, physical integrity and insecticide content of the LLINS, cross-sectional surveys were conducted at 18, 24 and 32 months after PermaNet 2 deployment in a malaria *Foci* in Guatemala. The surveys were standardized based on the WHO Guidelines. A total of 988 LLINs were analyzed (290 at 18 months, 349 at 24 months and 349 at 32 months). The overall survivorship of bednets decreased over time, 86% at 18 months, 76% at 24 months and 66% at 32 months. Independently of the time of the survey, less than 80% of the bednets that were still present in the household were reported to have been used the night before. A great percentage of the bednets had been washed at least once (88% at 18 months, 92% at 24 months and 96% at 32 months), and 60% of them were soaked, mainly with detergent powder. The physical inspection of the nets showed that the median total hole area (cm^2) in the bednets was 2.4 at 18 months, 8.4 at 24 months and 34.3 at 32 months. The proportion of bednets considered in good condition, according to the total hole surface area, diminished from 77% at 18 months to 58% at 32 months. The portion of LLINS with deltamethrin concentration less than 10mg/m^2, measured by bromine x-ray fluorescence, increased over time (14% at 18 months, 23% at 24 months, and 35% at 32 months). Among the bednets in where bioassays were conducted, the number of bednets that passed the WHO bioassay criterion of >=80% mortality at 24 hr. dropped from 90% at 18 months to 68% at 24 months and then 52% at 30 months. Even though the nets are in good physical condition at 32 months, its diminished bioefficacy compromises the protection provided to the user.

1877

WATER-LEVEL MANAGEMENT REDUCES MALARIA MOSQUITO ABUNDANCE AROUND LARGE DAMS IN SUB-SAHARAN AFRICA

Solomon Kibret[1], Glenn Wilson[2], Darren Ryder[3], Guiyun Yan[1]

[1]University of California Irvine, Irvine, CA, United States, [2]University of South Denmark, Odense, Denmark, [3]University of New England, Armidale, Australia

Water level management has been suggested as a potential tool to reduce malaria around large reservoirs. However, no field-based test has been conducted to assess the effect of water level management on mosquito larval abundance in African settings. The objective of the present study is to evaluate the effects of water level drawdown rates on mosquito larval abundance. Twelve experimental dams (5mx5mx1m) were constructed on the foreshore of the Koka Dam in Ethiopia. These were grouped into four daily water drawdown treatments, each with three replicates: no water-level drawdown (Group 1; Control), 10 $mm.d^{-1}$ (Group 2), 15 $mm.d^{-1}$ (Group 3) and 20 $mm.d^{-1}$ (Group 4). Larval sampling was conducted weekly for a period of 12 weeks each in the wet season (June - September) and subsequent dry season (January - April). A total of 1284 *Anopheles* mosquito larvae were collected from the experimental dams during the study period. Most (64%; n=822) were collected during the main malaria transmission season while the remaining (36%; n=463) were collected during the dry season. Larvae comprised four *Anopheles* species, dominated by *Anopheles arabiensis* (48%) and *An. pharoensis* (33.2%). Mean larval density was highest in control treatment dams with stable water levels throughout the study, and decreased significantly ($P < 0.05$) with increasing water drawdown rates in both seasons. During the main transmission season, anopheline larval density was generally lower by 30%, 70% and 84% in Groups 2, Group 3 and Group 4, respectively, compared with the control dams (Group 1). In the dry season, larval density was reduced by 45%, 70% and 84% in Groups 2, Group 3 and Group 4, respectively, when compared to the control dams. In conclusion, increased water drawdown rates were associated with lower mosquito larval abundance. Water level management could thus serve as a potential control measure for malaria vectors around reservoirs by regulating the persistence of shallow shoreline breeding habitats.

1878

INCIDENCE AND ETIOLOGY OF DIARRHEA IN CHILDREN: A TWO-YEAR ACTIVE SURVEILLANCE IN AN URBAN COMMUNITY OF VIETNAM

Nhi T. Le[1], Lam K. Phung[1], Corinne Thompson[1], Phat V. Voong[1], Nhu D. Tran[1], Trung D. Pham[1], Tuyen T. Ha[1], Nhan T. Nguyen[1], Tuyet T. Hoang[2], Chau V. Nguyen[3], Vi L. Lu[3], Tien T. Bui[2], Guy Thwaites[1], Stephen G. Baker[1]

[1]OUCRU Vietnam, Ho Chi Minh City, Vietnam, [2]Hung Vuong Hospital, Ho Chi Minh City, Vietnam, [3]The Hospital for Tropical Diseases, Ho Chi Minh City, Vietnam

Diarrheal diseases remain amongst the primary causes of the mortality among children under five years in low and middle-income countries. In Vietnam, the burden of hospitalised paediatric diarrheal disease is well-described; however, the true burden and aetiology of diarrheal disease in the community are not well documented. Between 2014 and 2016, we prospectively followed a cohort of 748 children aged between one and three years living in an urban area in Southern Vietnam. Active surveillance with SMS messaging and phone calls were conducted bi-weekly to caregivers to acquire further diarrheal disease episode in their children in the preceding seven days. Children with severe diarrhea were advised to visit a study hospital. Fecal samples were collected during the diarrheal episode at home or at hospital. These samples were then examined by microscopy for parasites, by culturing for bacterial pathogens, and by the Luminex xTAG Gastrointestinal Pathogen Panel assay to identify 15 pathogens. We measured 773 diarrhea episodes, of which 304 (39%) were hospitalised and 257 (33%) were severe and contained blood or mucus. The incidence of diarrhea significantly decreased with age ($p<0.001$) and was calculated as 721/1,000 child-years of observation (95%CI: 660-788). 433/628 (69%) fecal samples tested positive by Luminex; commonly identified bacteria and parasites included *Salmonella* (140, 32%), ETEC (82, 19%), *Clostridium difficile* (80, 18%), *Campylobacter* (63, 14%), *Shigella* (30, 7%), and *Cryptosporidium* (44, 10%). Commonly detected viral pathogens included *norovirus* (163, 37%), *adenovirus* (75, 17%), and *rotavirus* (69, 16%). We conclude that the incidence of paediatric diarrhea was high in this setting but decreased with age. We identified an abundance of pathogens known to be associated with moderate-to-severe paediatric diarrhea. Our work represents the most comprehensive cohort study of diarrhea disease conducted in children aged under 5 years in transitional Vietnam. Targeted age-specific interventions targeting common pathogens are necessary to prevent the morbidity from diarrheal disease among children in this setting.

1879

GEO-SPATIAL REPORTING OF CEFTRIAXONE RESISTANT *SALMONELLA TYPI* OUTBREAK INVESTIGATION IN HYDERABAD, PAKISTAN

Abdul Momin Kazi, Ayub Kazi, Tahir Yousafzai, Muhammad Khalid, Sultan Karim, Furqan Kabir, Shahida Qureshi, Farah Naz

Aga Khan University, Karachi, Pakistan

There are around 21 million cases and annually around 222,000 deaths occur related to typhoid. First case of ceftriaxone resistant Salmonella typhi was reported from Hyderabad, Pakistan in November 2016. We conducted a geospatial based outbreak investigation to identify the burden and spatial distribution of the outbreak using GIS mapping technique. A matched age case control study was conducted from 1st December 2016 to 15th September 2017 in Hyderabad. Data was collected through a structured questionnaire and drinking water samples were collected from household of cases and controls and from community water supplies for microbiological and molecular analysis. For geospatial mapping, Google Map® layer was integrated in the Esri ArcGIS version 10.5 to identify famous points and localities in Hyderabad. A paper based map of Hyderabad sewerage network was also acquired from Hyderabad water board which was scanned and georeferenced in the ArcGIS software. Further co-ordinates of the households for both cases and controls and important relevant landmarks including water supply were collected through a tablet. Color coding of positive and negative cases as well as water positive cases was conducted. A total of 486 ceftriaxone resistant S. typhi blood culture confirmed cases were identified. With the help of geospatial map, clustering of cases specifically around two areas of Hyderabad namely Qasimabad and Latifabad where identified. Further by incorporating different layers of data including sewerage lines, pattern of clustering along the water sewerage lines could be clearly seen. Lastly by plotting positive microbiology samples of community water we were able to show continuous shedding of bacterium in feces and contamination of water supplies by S. typhi patients. Based on the findings it is suggested to treat water sewage plants, safe potable water supply and mass vaccination to control outbreak.

MANAGEMENT OF DIARRHEA IN MALI: ASSESSMENT OF THE ADHERENCE TO WHO RECOMMENDATIONS IN THE VACCINE IMPACT ON DIARRHEA IN AFRICA (VIDA) STUDY

Doh Sanogo[1], Adama Mamby Keita[1], Anna Roose[2], Boubou Tamboura[1], Uma U. Onwuchekwa[1], Hellen Powell[2], Brehima Coulibaly[1], Milagritos D Tapia[2], Nasrin Dilruba[2], Samba Sow[1], Karen Kotloff[2]

[1]Centre pour le Dévélopement des Vaccins - Mali, Bamako, Mali, [2]CVD Baltimore, Maryland, Baltimore, MD, United States

Diarrheal diseases are a leading cause of under-five morbidity and mortality in developing countries. To improve management of pediatric diarrhea, WHO has provided treatment recommendations based on clinical syndromes and degree of dehydration as part of its Integrated Management of Childhood Illnesses approach. Here we assess practitioners' adherence to WHO recommendations for the treatment of diarrhea in Bamako, Mali among children who were enrolled in the Vaccine Impact on Diarrhea in Africa (VIDA) study. We identified children aged 0-59 months residing within two Bamako quartiers who were seeking care at a health center. Eligible children had a new episode (onset during the previous 7 days, after >7 diarrhea-free days) of moderate-to-severe diarrhea (diarrhea associated with sunken eyes, decreased skin turgor, dysentery, hospitalization, or IV rehydration). We assessed antibiotics, oral rehydration therapy (ORT), and zinc received or prescribed according to hydration status to determine the practitioners' adherence to WHO recommendation. From May 2015 to May 2017, 1227 eligible cases were enrolled. Among the cases 5% had "severe dehydration", 92% had "some dehydration" and 2% had "no dehydration." Most children presented with acute watery diarrhea (92%), followed by diarrhea with severe acute malnutrition (SAM, 5%) and dysentery (3%). ORT/IV antibiotics were given at the health center to 15% of children with diarrhea and SAM and 25% with severe dehydration associated with acute watery diarrhea or dysentery. Zinc was prescribed to 4% of the acute diarrhea cases; co-trimoxazole was the most widely prescribed antibiotic (72% of all cases). Only 8% cases of bloody diarrhea received a WHO-recommended antibiotic for dysentery and an additional 63% received co-trimoxazole. The management acute bloody and watery diarrhea are not in alignment with WHO recommendations for rehydration therapy, zinc, and antibiotics in Mali. Additional sensitization is needed to raise awareness about WHO recommended diarrhea case management.

1881

EVALUATING CHANGES IN DIARRHEA INCIDENCE AFTER 20 YEARS AMONG CHILDREN 0-59 MONTHS IN OSHIKHANDASS, GILGIT-BALTISTAN, PAKISTAN

Chelsea Hansen[1], Syed Iqbal Azam[2], Ejaz Hussain[1], Alexandra Jamison[1], Nahida Bano[2], Elizabeth D. Thomas[1], Sahrish Durrani[1], Julia Baker[1], Zeba Rasmussen[1]

[1]Division of International Epidemiology and Population Studies, Fogarty International Center, National Institutes of Health, Bethesda, MD, United States, [2]Aga Khan University Department of Community Health Sciences, Karachi, Pakistan

In 1989, diarrhea was the highest cause of childhood morbidity and mortality in Oshikhandass, a temperate climate region where the main water source was untreated glacier melt and toilet facility the traditional pit latrine. Interventions (water filtration plants, flush-toilets) were introduced from 1996-2002. Research Workers (RWs) trained in diarrhea management did weekly surveillance of children 0-59 months from 1989-1996 and classified diarrheal episodes by severity, gave treatment or referred, and followed up until recovery. Similar methods were utilized from 2011-2014. In the first study, 1843 children were followed for 4194 child-years (CY); 61.7% had at least one episode of diarrhea. In the second study, 1168 children were followed for 1567 CY; 43.2% had at least one episode of diarrhea ($p<.01$). Between the two study periods, diarrhea incidence remained unchanged at 0.7 episodes/CY. In the second study, children whose families migrated to Oshikhandass after 1995 had significantly higher incidence of diarrhea compared to those whose families had lived in the village during the first study (0.9 vs 0.7, RR: 1.3 95% CI: 1.2-1.5). Prevalence of diarrhea and mortality from diarrhea decreased significantly from 4.8 to 2.9 days/CY (RR: 0.61, 95% CI: 0.59-0.62) and 7 to 0.6 deaths/1000 CY (RR: 0.01, 95%CI: 0.00-0.09). Mean duration of diarrhea episodes decreased from 7.1 to 3.7 days ($p<.01$). In the first study 33.3% of episodes were prolonged (7-13 days), 8.5% were persistent (>=14 days), and 12.5% were bloody, compared to only 6.0%, 1.3%, and 5.4%, respectively, in the second study ($p<.01$). The highest incidence of diarrhea was in children 9-11 months of age in the first study (1.6 cases/CY, 95% CI: 1.4-1.7), and 18-20 months of age in the second study (1.3 cases/CY, 95% CI: 1.0-1.5). In both studies, diarrhea incidence was highest from May to September. Over the 20 years, incidence of diarrhea did not change, but mortality, mean duration, and severity decreased substantially, possibly because of improved SES including water and sanitation, and introduction of zinc. The percentage of children receiving ORS from health workers remained high.

1882

SYSTEMIC REVIEW OF OUTBREAKS DUE TO *SALMONELLA TYPHI* AND PARATYPHI IN AFRICA AND ASIA; CHALLENGES AND LIMITATIONS

Salman Haq[1], Rahima yasin[1], Asif khaliq[2], Tahir Yousufzai[2], Abdul Momin Kazi[2], Farah Naz Qamar[2]

[1]Ziauddin University Karachi, Karachi, Pakistan, [2]Aga Khan University Karachi, Karachi, Pakistan

Typhoid is a serious health issue, particularly in South Asia and in some regions of Africa. In addition to the high burden of endemic cases of the disease in these countries, outbreaks of typhoid pose a major challenge for the public health system. The recent outbreak of ceftriaxone resistant Salmonella Typhi in Pakistan led us to review the literature on typhoid outbreaks in Asia and regions of Africa to identify the case definitions, diagnostic criteria and methods used for outbreak control. We searched PubMed (1964-2018) for studies describing the outbreaks of Salmonella Typhi and Paratyphi A and B in Asia and Africa. Articles on mathematical modeling, papers describing laboratory methods of the outbreak strain were also excluded. Out of a total 185 relevant articles, only 38 met the eligibility criteria.Of these, 10 outbreaks were reported from Africa and 28 from Asia. Reports from Africa were from 7 countries , 60% (6/10) were from south Africa, Zimbabwe and Uganda. The reports from Asia were from 14 countries of which 28%(8/28) were from India. More than 80% of the outbreaks were reported between 2000-2017. Varying case definitions and lab methods were used for the outbreaks. In Africa 80% of the reports used some form of lab investigation to confirm the cases, 25% used serology, 87% used a combination of blood culture and PCR. In Asia 82% used a lab method for case confirmation. Most (86%) used stool and blood cultures. The source of the outbreak was identified in 50% outbreaks in Africa of which 80% were due to contaminated food. In Asia 14% were due to contaminated food and 44%(12/27) due to contaminated water. In Africa 30% of studies took steps to control the outbreaks. In Asia 35%(11/28) took outbreak response measures, of which 45%(5/11) used WSH methods and 27% (3/11) used health education. Typhoid vaccination as control measure was used in only one outbreak in Africa and 2 in Asia. This review highlights the importance of developing standardized case definition, laboratory confirmation and guidelines for outbreak response to use in response to typhoid outbreaks as currently there are none provided by the WHO or CDC.

1883

USING ARCGIS AND SATSCAN SOFTWARE TO INVESTIGATE EPIDEMIOLOGY AND RISK FACTORS OF ENTERIC INFECTIONS IN MIRPUR, BANGLADESH USING DATA FROM THE PROVIDE STUDY

Emily McPhee[1], Rashidul Haque[2], Mami Taniuchi[3], William A. Petri Jr[3], Beth Kirkpatrick[4], Priya Duggal[1], Poonum Korpe[1]

[1]Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States, [2]International Centre for Diarrhoeal Disease Research, Bangladesh, Dhaka, Bangladesh, [3]University of Virginia School of Medicine, Charlottesville, VA, United States, [4]University of Vermont College of Medicine, Burlington, VT, United States

Diarrheal disease is a leading cause of death in children under five years worldwide. In addition to a high mortality burden, diarrheal disease contributes to decreased oral vaccine efficacy and poor growth in children. Understanding risk factors, including geospatial distributions, associated with enteric pathogen transmission is essential to the design of interventions to prevent incident infections. To investigate these risk factors, data was collected on 700 infants from birth to 24 months of age in Mirpur, Bangladesh, through the PROVIDE study to examine associations between the spatial distributions of various enteric pathogen cases (*Rotavirus, Shigella, E. coli, Campylobacter, Cryptosporidium,* and *Giardia*) among PROVIDE participant households and SES factors such as monthly income, toilet type, and water source. Spatial clustering was analyzed through the use of a Bernoulli model in SaTScan software. Of the pathogens screened for in this population, *Rotavirus* was the only pathogen that exhibited significant spatial heterogeneity with 1 high-risk spatial cluster identified in the study area (relative risk = 2.18; p = 0.033). Additionally, though not statistically significant at the $\alpha = 0.05$ level, toilet sharing between households was implicated as the primary risk factor for both *Rotavirus* infection using a logistic regression model (OR: 1.69; 95% CI: 0.84 - 3.37; p = 0.140) and total pathogen burden using a Poisson model (IRR: 1.12; 95% CI: 0.99 - 1.27; p = 0.064).

1884

TRANSFER OF HEALTHY GUT FLORA FOR RESTORATION OF INTESTINAL MICROBIOTA VIA ENEMA (THRIVE) FOR THE REHABILITATIVE PHASE OF SEVERE ACUTE MALNUTRITION: METHODOLOGY FOR A NOVEL PILOT STUDY EVALUATING SAFETY, MICROBIAL ENGRAFTMENT AND NUTRITIONAL OUTCOMES

Majdi Osman[1], Caroline Zellmer[1], Elizabeth Goddard[2], Shiham Cader[3], Rob Knight[4], Zain Kassam[5], Mark Nicol[2], Heather Zar[2], Shrish Budree[2]

[1]OpenBiome, Somerville, MA, United States, [2]University of Cape Town, Cape Town, South Africa, [3]Red Cross War Memorial Children's Hospital, Cape Town, South Africa, [4]University of California, San Diego, San Diego, CA, United States, [5]Finch Therapeutics, Somerville, MA, United States

Severe acute malnutrition (SAM) remains an important challenge to child health globally. Accumulating evidence indicates that children with SAM have impaired development of their gut microbiota. This study aims to take the first translational step in evaluating the potential role of microbiota transfer therapy (MTT) as a broad-spectrum microbial therapy for uncomplicated SAM unresponsive to standard therapy. MTT, or fecal microbiota transplantation, has emerged as a safe and effective therapy for *Clostridium difficile* infection and has shown promise in repairing abnormal gut microbial community configurations related to other diseases such as inflammatory bowel disease, metabolic syndrome or autoimmune diseases. THRIVE is a single-center, two-armed, randomized controlled trial evaluating the safety of MTT administered via enema (followed by standard of care) in South African children aged 18-60 months in the recovery phase of SAM. MTT is minimally processed stool from a screened healthy donor. Twenty children presenting to hospitals in Cape Town, South Africa who meet the inclusion criteria will be randomized 1:1 to receive MTT by enema and standard of care or standard of care only. Treatment will be dosed at 10mL/kg (maximum 150mL) of donor fecal material followed by standard ready-to-use therapeutic food. Children in the control arm who show no nutritional recovery at 8 weeks despite adequate nutritional intake will be offered MTT provided they continue to meet the inclusion criteria. Children will be evaluated through 8 weeks after randomization. Children will be assessed for the primary outcome of safety and secondary outcomes including microbial engraftment, biomarkers associated with recovery in SAM, nutritional and clinical endpoints. Stool samples will be collected at enrollment and on days 3, 7, 21 and 56 and analyzed using 16S rRNA sequencing and whole genome sequencing. This is the first study exploring broad-spectrum microbiome manipulation for SAM and could open novel therapeutic avenues for children with SAM poorly responsive to standard therapy.

1885

ETIOLOGY, CLINICAL SEVERITY AND ENTEROAGGREGATIVE *ESCHERICHIA COLI* ASSOCIATED WITH DIARRHEAL DISEASES IN INFANTS AT SEMIARID REGION IN BRAZIL: A CASE-CONTROL STUDY

Aldo A. Lima[1], Alexandre Havt[1], Mara M. Prata[1], Pedro H. Quintela[1], Ana K. Santos[1], Herlice N. Veras[1], Rafaela C. Pankov[1], Mariana D. Bona[1], Eric R. Houpt[2], Richard L. Guerrant[2]

[1]Federal University of Ceara, Fortaleza, Brazil, [2]University of Virginia, Charlottesville, VA, United States

Diarrheal diseases are important cause of morbidity and mortality in children in developing countries. We aim to study the etiology and severity of diarrheal disease in children in the low-income Brazil semiarid region. This is a cross-sectional study, age-matched case-control of diarrhea in children aged 2-36 months residing in six cities from Brazil semiarid region. After informed consent from their parents or guardians, clinical and epidemiological data, anthropometric measurements, and a fecal sample collected to identify enteropathogens (Luminex Bio-Plex 200 System, Bio-Rad, USA). Positive EAEC samples were further analyzed using multiplex PCRs targeting 27 virulence related genes (VRGs). We enrolled 1,200 children, 596 diarrhea cases and 604 controls. By logistic regression including all enteropathogens, the best predictors of diarrhea were six pathogens in descending order: *Norovirus*, *Adenovirus*, *Rotavirus*, STEC, *Giardia* and EAEC. Severity diarrhea score was significantly associated with EAEC ($p < 0.001$). EAEC VRGs analysis showed *espC* gene (cytotoxic serine protease autotransporter) was associated with diarrhea (p=0.025, OR 1.82, 95% CI 1.07 3.11), and *agg4A* gene (AAF/IV fimbria unit) was associated with controls (p = 0.011, OR 0.47 95% CI 0.26 0.85). In addition, *espC* gene was further associated with increased diarrhea severity (p=0.001), while *aar* gene (negative regulator of AggR) was associated with less severity (p=0.025). Six enteropathogens, *Norovirus*, *Adenovirus*, *Rotavirus*, STEC, *Giardia* and EAEC are associated with diarrhea in children in the low-income Brazil semiarid region. EAEC was associated with diarrhea severity score, with further contribution of specific VRGs profile *espC*(+) and *aar*(-).

1886

THE CRITICAL ROLE OF ZINC IN A NEW MURINE MODEL OF ENTEROTOXIGENIC *ESCHERICHIA COLI* DIARRHEA

David D. Bolick[1], Pedro H. Medeiros[2], Ellen Ledwaba[1], Aldo A. Lima[2], James P. Nataro[1], Eillen Barry[1], Richard L. Guerrant[1]

[1]University of Virginia, Charlottesville, VA, United States, [2]Universidade Federal do Ceará, Fortaleza, Brazil

Enterotoxigenic *E. coli* are major causes of traveler's diarrhea as well as endemic diarrhea and stunting in children in developing areas. However, a small mammal model has been badly needed to better understand and assess mechanisms, vaccines and interventions. We report a murine model of ETEC diarrhea, weight loss and enteropathy, and investigate the role of zinc on the outcomes. LT+ST producing enterotoxigenic *E. coli* (ETEC) given to weaned C57BL/6 mice after antibiotic disruption of normal microbiota cause growth impairment, watery diarrhea, heavy stool shedding and mild to moderate intestinal inflammation, the latter worse with zinc deficiency. Zinc treatment promoted growth in zinc deficient infected mice, and subinhibitory zinc reduced expression of ETEC virulence genes *cfa1*, *cexE*, *sta2* and *degP*, but not *eltA in vitro.* Zinc supplementation increased shedding and ileal burden of WT ETEC, but decreased shedding and tissue burden of LTKO ETEC. LTKO also caused less inflammation by fecal MPO assessment, all suggesting that, in contrast to LT which is more associated with colonization and early diarrhea, ST expression is increased with ZD and is responsible for greater inflammation. These findings provide a new murine model of ETEC infection that can help elucidate mechanisms of growth, diarrhea and inflammatory responses as well as potential vaccines and interventions.

1887

CAMPYLOBACTER JEJUNI INFECTION AND HOUSEHOLD-LEVEL FACTORS ARE ASSOCIATED WITH CHILDHOOD GROWTH IN MIRPUR, BANGLADESH: AN ANALYSIS OF THE MAL-ED STUDY

J. Johanna Sanchez[1], Md. Ashraful Alam[2], Mohammad Jyoti Raihan[2], Md. Ahshanul Haque[2], Subhasish Das[2], Mustafa Mahfuz[2], Christopher B. Stride[3], Peter Sly[1], Kurt Z. Long[4], Tahmeed Ahmed[2]

[1]University of Queensland, Brisbane, Australia, [2]International Centre for Diarrhoeal Disease Research, Bangladesh, Dhaka, Bangladesh, [3]University of Sheffield, Sheffield, United Kingdom, [4]Swiss Tropical and Public Health Institute, Basel, Switzerland

The dual burden of enteropathogen infection and childhood malnutrition continues to be a global health concern and a leading cause of morbidity and death among children. *C. jejuni* infection, in particular, continues to be highly prevalent in low and middle income countries, including Bangladesh. We examine longitudinal data to evaluate the trajectories of change in child growth, and identify the association with *C. jejuni* infection and household-level factors. The study analyzed data from 265 children participating in the Etiology, Risk Factors, and Interaction of Enteric Infections and Malnutrition and Consequences for Child Health (MAL-ED) Study in Mirpur, Bangladesh. We applied latent growth curve modelling to evaluate the trajectories of change in height, as measured by height-for-age z-score (HAZ), amongst children 0-24 months of age. Household-level risk factors were included in the model as time-invariant covariates. Asymptomatic and symptomatic *C. jejuni* infections were included as lagged time-varying covariates. An inverse association was found between increasing age and HAZ. Greater maternal education, improved water source, and treatment of water were positively associated with HAZ. *C.jejuni* infection was more prevalent with increasing age, with over 70% of children 18-24 months of age testing positive for infection. A positive episode of infection in the preceding three-month interval was associated with decreased HAZ at 12, 15, and 18 months of age. The results indicate that maternal education and household-level factors have a positive effect on child growth trajectory while *C. jejuni* infection has a negative effect on HAZ at specific age intervals. Further analyses will explore the relationships between the household-level factors and *C. jejuni* infection.

IDENTIFYING TRANSMISSION ROUTES FOR CHOLERA INFECTIONS AMONG HOUSEHOLD CONTACTS OF CHOLERA PATIENTS IN RURAL BANGLADESH

Christine Marie George[1], Khaled Hasan[1], Shirajum Monira[2], Zillur Rahman[2], K. M. Saif-Ur-Rahman[2], Mahamud Rashid[2], Fatema Zohura[2], Tahmina Parvin[2], Md. Sazzadul Islam Bhuyian[2], Toslim T Mahmud[2], Jamie Perin[1], Shan Li[3], Camille Morgan[1], Munshi Mustafiz[2], R. Bradley Sack[1], David Sack[1], Colin Stine[3], Munirul Alam[2]

[1]Johns Hopkins University, Baltimore, MD, United States, [2]International Centre for Diarrhoeal Disease Research, Bangladesh, Dhaka, Bangladesh, [3]University of Maryland School of Medicine, Baltimore, MD, United States

Household contacts of cholera patients are at a 100 times higher risk of developing cholera than the general population. The objective of this study is to examine the incidence of cholera infections among household contacts of cholera patients in a rural setting, to identify risk factors for cholera infections among this population, and to investigate cholera transmission pathways using multilocus-variable-number-tandem-repeat-analysis (MLVA). This approach allowed for intervention strategies to be identified that could be used to reduce the incidence of cholera among household contacts of cholera patients. Stool from household contacts and water source and stored water samples were collected from cholera patient households at Day 1, 3, 5, and 7 after the presentation of the index patient at a health facility. Two hundred thirty clinical and water

isolates were analyzed by MLVA. Thirty-seven percent of households had at least one household contact with a cholera infection. Thirteen percent of households had *V. cholerae* in their water source, and 27% had *V. cholerae* in stored household drinking water. Household contacts with *V. cholerae* in their water source had a significantly higher odds of a symptomatic cholera [Odds Ratio (OR): 5.49, 95% Confidence Interval (CI): 1.07, 28.08]. Contacts consuming street vended food had a significantly higher odds of a cholera infection (OR: 9.45, 95% CI: 2.14, 41.72). Older age was significantly associated with a lower odds of a cholera infection (OR: 0.96, 95% CI: 0.93, 0.99). All households had clinical and water isolate that were closely related by MLVA. These findings emphasize the need for interventions targeting water treatment and food hygiene to reduce cholera infections.

1889

MODELLING THAI POPULATION DYNAMICS AND SEASONAL MOVEMENT TO ASSESS AND PREDICT THE BURDEN OF MELIOIDOSIS

Wiriya Mahikul

Mahidol University, Bangkok, Thailand

Thailand demography is in the transient phase with the aged population doubling within a decade. Melioidosis is a communicable disease, with transmission from environment, especially soil and water, with 4.96/100,000 reported cases in 2015, and eight-fold in rural areas compared to urban areas. Changes in the population structure and social impacts of life style changes reflecting in seasonal movement, and urbanization are hypothesized to significantly influence the incidence of melioidosis. Our objective is to examine changes in the age, sex, diabetes, and seasonal movement on melioidosis using mathematical modelling. A dynamic model was constructed including demographic and disease processes. The model was fitted to incidence of reported melioidosis among males and females using a Bayesian Markov chain Monte Carlo (MCMC) approach to accurately assess uncertainty in parameters of disease onset, progression, and reporting. Our model predicted higher incidence rates of melioidosis compared with the national surveillance data, reflecting under-reporting issue. Transient populations and working ages are the highest risk groups. The estimated of incidence rates among males was two-fold greater than that of females, moreover, the incidence rates in rural area was more than double compared to urban area. The predicted annual incidence rate of melioidosis between 2008-2035 was 22.1 to 23.8/100,000 with a slightly increasing trend. The estimated population mortality rate was 3.67 to 3.86, compared with 3.45 reported per 100,000 people in 2015. Our results show the incidence rates among people with diabetes was two-fold greater than those non-diabetes. Transient populations, males aged ≥ 45 years, living in a rural area, and diabetes (diagnosed or not) diabetes were independent risk factors for melioidosis. The study helps assessing the impacts of changing population structure and diabetics on melioidosis epidemiology in Thailand. The model is useful to identify high risk groups and to guide targeted strategies to disease prevention and control.

1890

SPATIOTEMPORAL DYNAMICS OF *STREPTOCOCCUS PNEUMONIAE* IN RURAL PAKISTAN

Benjamin M. Althouse[1], Imran Nisar[2], Fyezah Jehan[2], Sheraz Ahmed Ahmed[2], Furqan Kabir[2], Sadia Shakoor[2], Asad Ali[2], Najeeha Iqbal[2], Hao Hu[1]

[1]Institute for Disease Modeling, Bellevue, WA, United States, [2]Aga Khan University, Karachi, Pakistan

Background and aimsKnowing how S. pneumococcus (SP) carriage varies in time and space aides in rollout of new vaccination programs through identifying potential 'hotspots' of transmission as well as estimating the level of herd-protection induced by those vaccination programs. Largely, these spatiotemporal dynamics are underexplored in developing settings. MethodsAn ongoing NP carriage survey near Karachi, Pakistan randomly selects 60 infants per month and gathers information on illness indicators, socioeconomic status, and household demographics, and records the spatial coordinates of each individual. These data were modeled as spatial point patterns and space-time clusters were identified using Ripley's K function. ResultsSignificant clusters were observed over the study area across three years. Over time, the physical distance between children vaccinated with PCV and vaccine-type SP carriage increased, giving an indirect estimate of herd immunity induced by PCV. ConclusionsClear spatiotemporal patterns of SP carriage exist in rural Pakistan, and are associated with PCV vaccinated individuals, indicating the need for uniform vaccination coverage when introducing it to new populations.

1891

DEVELOPMENT AND EVALUATION OF A LABORATORY-DEVELOPED TAQMAN ARRAY CARD (TAC) FOR ANTIMICROBIAL RESISTANCE (AMR) DETECTION

Suporn Pholwat[1], Jie Liu[1], Mami Taniuchi[1], Iyarit Thaipisutikul[2], Parnthep Ratanakorn[3], Suporn Foongladda[2], Eric Houpt[1]

[1]Division of Infectious Diseases and International Health, Department of Medicine, University of Virginia, Charlottesville, VA, United States, [2]Department of Microbiology, Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand, [3]Faculty of Veterinary Science, Mahidol University, Nakhonpathom, Thailand

Antimicrobial resistance (AMR) is a significant public health issue worldwide. Monitoring and surveillance of resistance is one action for addressing and preventing AMR. Phenotypic antimicrobial susceptibility testing is laborious and unable to test multiple antimicrobial agents simultaneously. A rapid high throughput AMR detection tool will be useful to monitor AMR prevalence. We designed and developed an easy-to-perform genotypic TaqMan array card with 89 sequences specific PCR reactions to detect 85 antimicrobial resistance associated genes or mutations for 10 highly important antimicrobial classes used in human and veterinary medicine. This included cephalosporins, quinolones, macrolides, penicillins, aminoglycosides, polymyxins, folate pathway inhibitors, tetracyclines, phenicols and carbapenems. The 89 qPCR assays were tested for performance against 251 well characterized (genotypic) antibacterial resistance isolates, which included 201 isolates from the FDA-CDC AR bank (CDC, Atlanta, GA, USA), 15 isolates from Antibacterial Resistance Leaderships Group (ARLG, Durham, NC, USA), and 35 isolates from American Type Culture Collection (ATCC, Manassas, VA, USA) on 384 well PCR plates. Sanger sequencing was performed for confirmation when discordances were observed. The 89 assays revealed near-perfect concordance on the 251 isolates (i.e., 2244 true positives, 20081 true negatives, 11 discrepant). Comparing the association between genotypic and phenotypic DST of 38 *E. coli* isolates for 22 antimicrobial agents, we observed an overall sensitivity of 75-100% across the 22 drugs, specificity 55-100%, and accuracy 74-97%. Sensitivity was lowest for β-lactam/β-lactamase inhibitors, and specificity low for aztreonam, ciprofloxacin, aminoglycosides and sulfamethoxazole. Kappa agreement ranged from moderate to almost perfect between the two methods (κ = 0.44 – 0.91). Accepting certain genotypic-phenotypic discrepancies that are manageable, this TaqMan array card yields an accurate susceptibility result compared to the standard phenotypic DST.

1892

DRY REAGENT-BASED LOOP-MEDIATED ISOTHERMAL AMPLIFICATION FOR CONFIRMATION OF BURULI ULCER USING A PORTABLE FLUORIMETER

Marcus Beissner[1], Dziedzom K. de Souza[2], Issaka Maman[3], Malkin Saar[1], Katrin Zwirglmaier[4], Franz X. Wiedemann[5], Gisela Bretzel[1], Joseph M. Ndung'u[6], **Israel Cruz**[6], Anthony Ablordey[2]

[1]Department of Infectious Diseases and Tropical Medicine (DITM), University Hospital, Ludwig-Maximilians-University, Munich, Germany,

[2]Noguchi Memorial Institute for Medical Research (NMIMR), University of Ghana, Accra, Ghana, [3]Institut National d'Hygiène, Lomé, Togo, [4]Bundeswehr Institute of Microbiology, Munich, Germany, [5]German Leprosy and Tuberculosis Relief Association, Togo office, Lomé, Togo, [6]FIND, Geneva, Switzerland

Early diagnosis and treatment of Buruli ulcer (BU), a necrotizing skin infection caused by *Mycobacterium ulcerans* (MU), are crucial for case management and disease control. The use of IS*2404* PCR is recommended for laboratory confirmation of BU, but this requires well-equipped laboratories and is thus restricted to reference centres in endemic countries. As the highest burden of BU is in rural areas, point-of-care molecular diagnostic tests are urgently needed. Loop-mediated isothermal amplification (LAMP) is considered an appropriate technology for microscopy level laboratories. This study optimizes and evaluates a dry reagent-based (DRB) LAMP test for detection of MU DNA (IS*2404*) using a portable fluorimeter. Two IS*2404* LAMP primer sets were analysed using freeze-dried LAMP chemistries from OptiGene and Lucigen. A Genie III fluorimeter (OptiGene) was used for isothermal amplification, detection of LAMP products and confirmation of amplicon specificity by annealing curve analysis. Different freeze-dried primer/chemistry combinations were prepared and their performance assessed by analysis of specificity, sensitivity and time to positivity (Tp) using serial dilutions of IS*2404* plasmid standards, MU culture extracts and DNA extracts derived from swab and fine-needle aspirate samples from BU suspected cases, as well as must-not-detect samples from leprosy patients. Both primer combinations using OptiGene chemistry detected MU DNA in all MU culture extracts and clinical BU samples, and showed 100% specificity. The limit of detection was 5 and 0.5 MU genome equivalents, with 78% and 100% sensitivity in clinical samples depending on the primer set. The Tp ranged from 3 to 19. Freeze-dried primer combinations using Lucigen chemistry did not yield any positive result under our laboratory conditions. The optimized DRB LAMP test was highly specific, sensitive and robust and will now be subjected to large-scale evaluation. DRB-LAMP will contribute in filling the gap in confirmatory diagnosis that exists between reference centres and endemic *Foci* in rural areas.

1893

MOLECULAR MARKERS OF ANTIMICROBIAL RESISTANCE IN *NEISSERIA GONORRHOEAE* ISOLATES FROM GHANA

Naiki Attram[1], Bright Agbodzi[2], Helena Dela[2], Eric Behene[2], Edward Owusu Nyarko[3], Nicholas Nana Adjei Kyei[3], Kennedy Kwasi Addo[2], Christopher Anthony Duplessis[4], Nehkonti Adams[5], Andrew Gordon Letizia[6]

[1]Naval Medical Research Unit Number Three Ghana Detachment/Noguchi Memorial Institute for Medical Research, Accra, Ghana, [2]Noguchi Memorial Institute for Medical Research, Accra, Ghana, [3]Ghana Armed Forces Public Health Department, Accra, Ghana, [4]Naval Medical Research Center, Maryland, MD, United States, [5]Navy Medicine Professional Development Center, Maryland, MD, United States, [6]Naval Medical Research Unit Number Three Ghana Detachment, Accra, Ghana

Antimicrobial resistance (AMR) to *Neisseria gonorrhoeae* is evolving. In Ghana, gonorrhea is treated empirically, little is known about the resistance status of circulating gonococci. Identifying AMR, molecular mechanisms of resistance and *Neisseria gonorrhoeae* multiantigen sequence types (NG-MAST), are important for guiding treatment and detecting the emergence of new molecular mechanisms of resistance. There is no published record of NG-MASTs. Forty-nine isolates were collected during 2012-2015. After obtaining informed consent, a urethral swab (males) or an endocervical swab (females) was collected from patients presenting at two health facilities in Accra and three others in Sekondi and Takoradi with urethral or vaginal discharge, dysuria and intermenstrual bleeding in women, as well as abdominal pain. Each swab was inoculated on Modified Thayer Martin (MTM) agar. The agar plate was incubated at 25-27°C for 24-72 hours and checked for growth every 18-24 hours. Gonococcal isolates were identified by Gram stain, oxidase, catalase and the API-NH tests. Resistance to penicillin, tetracycline, ciprofloxacin, azithromycin, cefixime, ceftriaxone and spectinomycin was tested with the disc diffusion method and the E-test. NG-MASTs were determined. Resistance determinants to penicillin, cefixime, ceftriaxone (bla_{TEM}, *penA,* MtrR*, ponA*) and ciprofloxacin (*parC* and *GyrA*) were detected. A total 11 NG-MASTs were seen, an additional 17 were novel. The only multidrug resistant (MDR) isolate was ST1407. Isolates had either a bla_{TEM-1} or a $bla_{TEM-135}$ gene. Six *penA* amino acid sequence patterns, II, XVIII, XIV, XIX, XII and XXXIV were detected. In the MtrR repressor, the following mutations were seen, A39T, G45D and G45S as well as L421P in the *ponA* gene. Substitutions, S91F, D95A and D95G were seen in the *gyrA* regions, and D86N, S87N and E91G in the *parC* regions. Data shows genetic diversity: one isolate belongs to ST1407, which has been circulating globally with high MICs to the extended spectrum cephalosporins. This is the first report of an isolate with reduced susceptibility to cefixime in Ghana. There is a need for continued AMR surveillance.

1894

SURVEILLANCE OF ESBL-PRODUCING *KLEBSIELLA PNEUMONIAE* IN SAMPLES OBTAINED FROM TWO HOSPITALS IN THE PERUVIAN AMAZON

Rosa Burga[1], Ricardo Abadie[1], Claudio Rocha[1], Cesar Ramal[2], James Regeimbal[1], Andrea McCoy[1]

[1]Naval Medical Research Unit-6, Lima, Peru, [2]Hospital Regional de Loreto, Iquitos, Peru

Infections caused by Gram negative bacteria are highly prevalent in hospitalized patients, especially in intensive care units. However, multidrug resistant strains represent a therapeutic challenge for both community and hospital-acquired infections, leaving very few and often undesirable options for treatment. It is estimated that between 50% and 60% of the more than two million hospital-adquired infections in the United States per year are caused by resistant bacteria, leading to nearly 77,000 deaths annually. Bacterial resistance also continues to increase globally. Extended-spectrum beta-lactamases (ESBL) are of particular significance as they confer resistance to a large group of beta-lactam antibiotics, especially carbapenems, 3rd generation cephalosporins, monobactams and to a lesser but stillimportant extent the aminoglycosides. In the present study conducted from January 2016 to February 2018, 172 samples were collected and processed following standart laboratory procedures for identification and AST determination. Of those samples, 158 (92%) were positive to some pathogen: *E. coli* was the most common pathogen isolated, 70 (46%), followed by *Klebsiella pneumoniae,* 37 (24%), of which 26 (70%) were ESBL producers. Susceptibility test revealed a high resistance to Ceftriazone (100%) and Aztreonam (88%), and a high sensitivity to Imipenem (100%). These results indicate that treatment strategies in the Amazon region of Peru should reflect emerging resistances and ESBL producing strains.

1895

PREVALENCE OF ESKAPE PATHOGENS AND THEIR ANTIMICROBIAL RESISTANT IN WOUND INFECTIONS FROM HOSPITALIZED PATIENTS IN THE PERUVIAN AMAZON CITY OF IQUITOS

Ricardo E. Abadie Saenz[1], Rosa Burga[1], Claudio Rocha[1], Karla Vilela[1], Cesar Ramal[2], Moises Sihuincha[3], Veronica Chicata[4], James Regeimbal[1], Andrea McCoy[1]

[1]U.S. Naval Medical Research Unit-6, Lima, Peru, [2]Hospital Regional Loreto, Iquitos, Peru, [3]Hospital Apoyo Iquitos, Iquitos, Peru, [4]Hospital Militar Divisionario Santa Rosa, Iquitos, Peru

Wound infections caused by multi-drug resistant (MDR) ESKAPE pathogens (*Enterococcus faecalis, Staphylococcus aureus, Klebsiella pneumoniae, Acinetobacter baumannii, Pseudomonas aeruginosa and Enterobacter spp.)* are an increasing problem in both military and civilian populations.

Iquitos is a geographically isolated city in the Peruvian Amazon with little information regarding prevalence and antimicrobial resistance of the ESKAPEs. From July 2017 to February 2018, 180 wound samples (160 civilian; 20 military) were taken from hospitalized patients in Iquitos; 134 of which were culture-positive with 59% (79/134) yielding ESKAPE strains. In total, 229 bacterial strains were isolated, of which 40.6% (93/229) were ESKAPEs. *S. aureus* was the most common with 36 isolates (36/93, 39%), followed by *K. pneumoniae* (27%,25), *P. aeruginosa* (14%, 13), *A. baumannii* (10%, 9), *E. cloacae* (9%, 8), and finally *E. faecium* (2%, 2). Of *S. aureus* isolates, 94% (34/36) were resistand to Penicillin, 19% (7/36) were resistant to Azithromycin and Tetracycline, 17% (6/36) were methicillin resistant; 8% (3/36) to Ciprofloxacin and Clindamycin, and 8% (3/36) showed inducible clindamycin resistance. 80% (20/25) of all *K. pneumoniae* isilates were ESBL-producing; 88% (22/25) were resistant to Trimethoprim/sulfamethoxazole, 68% (17/25) to Tetracycline, 60% (15/25) to Gentamicin, 40% (10/25) to Ciprofloxacin with 48% (12/25) intermediate, and only 8% (2/25) were resistant to Amikacin. 38% (5/13) of *P. aeruginosa* isolates were MDR ande 31% (4/13) were Imipenem resistant. 67% (6/9) of *A. baumannii* isolates were MDR and 11% (1/9) was imipenem resistant. These high rates of antimicrobial resitance represent a serious public health concern for wounded and hospitalized patients, and emphasize the need for continued resistance surveillance in Peru and developing countries.

1896

RESURGENCE OF DIPHTHERIA IN HAITI: OBSERVATIONS FROM THE NATIONAL EPIDEMIOLOGIC SURVEILLANCE SYSTEM: 2014 - 2018

Stanley Juin

Centers for Disease Control and Prevention, Port-au-Prince, Haiti

Diphtheria is a vaccine-preventable disease caused by toxin-producing *Corynebacterium diphtheriae*. Globally, diphtheria cases have declined due to improvements in childhood vaccination coverage. In Haiti, childhood immunization coverage with a diphtheria vaccine has perennially been below 70%. Since August 2014, Haiti has experienced a resurgence in diphtheria cases. We reviewed epidemiological data from 2014-2018. We defined a probable case as pharyngitis, tonsillitis, or laryngitis and the presence of a pseudomembrane; a confirmed case was a probable case with laboratory confirmation of toxin-producing *C. diphtheriae* by PCR, or a probable case with epidemiologic link to a laboratory-confirmed case. From August 2014 to March 2018, 456 probable diphtheria cases were notified to the Ministry of Health (MOH), from the ten geographic departments of the country. The Median age was 8 years (IQR: 5, 11), 263 (58%) were female. Of 456 probable cases, 374 (82%) were tested by reverse transcriptase PCR and 189 (51%) were positive. Laboratory-confirmed cases have a median age of 8 year old (IQR: 5, 11); 182 (96%) were younger than 18 years and, of these, 145 (80%) were unimmunized against diphtheria. Among confirmed PCR positives, 152/189 (80%) had no history of immunization. Of patients tested by PCR, among those with no history of immunization 151/270 (56%) were PCR positive, whereas among those who received at least one dose of vaccine 38/104 (37%) were PCR positive ($p<0.00005$). Of PCR positives, 14% received diphtheria antitoxin (DAT) for treatment. The case fatality rate among confirmed case was 40/189 (21%). In response to the outbreak, the MOH has strengthened laboratory testing capacity, provided awareness, case management and outbreak response activities, improved access to diphtheria antitoxin and is conducting diphtheria supplemental immunization activities. The current surge of diphtheria cases emphasizes the need for ongoing enhanced surveillance, laboratory testing capacity, awareness among health providers, and ensuring availability of DAT.

1897

WHOLE-GENOME ANALYSIS OF *BURKHOLDERIA PSEUDOMALLEI* ISOLATE ASSOCIATED WITH A CONFIRMED CASE OF MELIOIDOSIS IN PERU

Ronnie G. Gavilan, Eduardo Juscamayta-Lopez, Juan J. Ramirez

Instituto Nacional de Salud, Lima, Peru

Burkholderia pseudomallei is a gram-negative bacterium that causes the fatal disease melioidosis. An increasing number of melioidosis cases are being reported in tropical regions, including Latin America countries. In this study, we report the whole-genome analysis of Burkholderia pseudomallei isolate associated with the first confirmed case of Melioidosis in the northern of Peru. An isolate of B. pseudomallei from a clinical case of melioidosis was sequenced using both Miseq Illumina and MinION Oxford Nanopore. The raw sequences were assembled using is hybrid assembly pipeline Unicycler and gene annotation was performed using web platform RAST. Genomic sequences of global B. pseudomallei isolates were retrieved from GenBank. Phylogenomic analysis based on SNPs of the core genome was inferred with RAxML v8.2.9 using the Maximum Likelihood method and under the general evolutionary model GTR with 1000 bootstrap. Genomic analysis allow to complete the whole genome of this isolate divided in two chromosomes and also confirm the presence of a novel variant of Class D β-lactamase OXA-57 associated with multidrug-resistance. Phylogenomic reconstruction revealed that Peruvian isolate grouped into a single clade including isolates form Brasil and Ecuador resulting in the Latin America lineage based on highly informative SNPs. Overall genomic and epidemiological data confirm the report of novel multidrug-resistant Burkholderia pseudomallei isolate associated with a fatal case in Peru that would be particularly relevant in respect of the melioidosis as emerging diseases posing as public health risk.

1898

EMERGING *BARTONELLA BACILLIFORMIS*, *LEPTOSPIRA* SPP., AND *RICKETTSIA* SPP. IN THE SOUTHEASTERN PERUVIAN AMAZON BASIN

Juana M. del Valle[1], Fiorella Ricapa-Antay[1], Katia Díaz-Melón[1], Fernando Vásquez-Achaya[2], Wilmer Silva-Caso[2], Miguel Angel Aguilar-Luis[3], Luis J. del Valle[4], Carlos Palomares-Reyes[2], Pablo Weilg[1], Carlos Manrique[5]

[1]Universidad Peruana de Ciencias Aplicadas, Lima, Peru, [2]Universidad Peruana de Ciencias Aplicadas, Instituto de Investigación Nutricional, Lima, Peru, [3]Universidad Peruana de Ciencias Aplicadas, Instituto de Investigación Nutricional, Instituto de Investigación de Enfermedades Infecciosas, Lima, Peru, [4]Universidad Politécnica de Catalunya, Barcelona, Spain, [5]Dirección Regional de Salud Madre de Dios, Madre de Dios, Peru

Acute febrile illnesses (AFI) represent a major health problem in the Peruvian Amazon basin due to their diverse etiologies and low laboratory-confirmation rates. Madre de Dios is one of the most affected regions in Peru endemic for dengue, leptospirosis among other causes of AFI such as bartonellosis and rickettsiosis that remain under-reported. This study was undertaken to detect via PCR the presence of *Leptospira* spp., *Bartonella bacilliformis* and *Rickettsia* spp. in serum samples from patients with AFI from Madre de Dios, Peru. Blood samples from patients with acute febrile illness were analysis by real-time PCR for detection the presence of *Bartonella bacilliformis*, *Leptospira* spp. and *Rickettsia* spp. *Bartonella bacilliformis* was the most prevalent bacteria isolated in 21.6% (30/139) of samples, followed by *Leptospira* spp. in 11.5% (16/139) and *Rickettsia* spp. in 9 cases. No coinfections were observed between these bacteria. The most frequent symptoms associated with fever were headaches, myalgias and arthralgias across all groups, with no significant difference between the three bacteria clinical presentation. In conclusion, in our study series, *B. bacilliformis* is the most common pathogen isolated in patients

with AFI. The unspecific presentation of these bacteria highlights the need for laboratory-confirmation to strength the Peruvian epidemiological surveillance.

1899

RETROSPECTIVE COHORT STUDY OF TYPHOID AND PARATYPHOID FEVER AT REFERRAL CENTER FOR TRAVEL AND TROPICAL DISEASES IN JAPAN

Taiichiro Kobayashi[1], Masatomo Morita[2], Kazuaki Fukushima[1], Masaru Tanaka[1], Noritaka Sekiya[3], Keishiro Yajima[1], Atsushi Ajisawa[1], Hidemasa Izumiya[2], Akifumi Imamura[1]

[1]Department of Infectious Diseases, Tokyo Metropolitan Cancer and Infectious Diseases Center Komagome Hospital, Tokyo, Japan, [2]Department of Bacteriology I, National Institute of Infectious Diseases, Tokyo, Japan, [3]Department of Infection Prevention and Control, Department of Clinical Laboratory, Tokyo Metropolitan Cancer and Infectious Diseases Center Komagome Hospital, Tokyo, Japan

Typhoid and paratyphoid fever are rare infectious diseases in Japan. Moreover, the treatment is complicated mainly because of drug resistance. The aim of this study is to demonstrate the clinical characteristics of typhoid and paratyphoid fever at referral center for tropical infectious diseases in Japan. We reviewed medical records of the patients with typhoid or paratyphoid fever who were treated at our institute between 2000 and 2017. Patients with *Salmonella enterica* serovar Typhi or *S. enterica* serovar Paratyphi A isolated from any specimens were included. There were 32 typhoid fever cases and 23 paratyphoid fever cases. The median age was 25 years (interquartile range, 22-37 years), 60% were male and the majority was Japanese (76%). Ninety-five percent (52/55) were imported cases. Fifty-eight percent (32/55) were from South Asian countries and 33% (18/55) were from Southeast Asian countries. Eighty-nine percent were diagnosed by blood culture, and the median time to blood culture positivity was 1 day. Nine percent (5/55) were suspected multi-drug resistant (MDR) and all MDR suspected cases were typhoid fever infected in South Asian countries. Sixty-four percent were nalidixic acid (NA) resistant, which means low-level fluoroquinolone resistant, and 87% of strains from South Asian countries were NA resistant. All 3 relapsed cases were mainly treated by cephalosporin, and the relapse rate of cephalosporin treatment was 10%. There was no fatal case. Nowadays, rate of MDR cases has already declined, so the most can be treated by the conventional drug of choice, for example sulfamethoxazole/trimethoprim and ampicillin. On the other hand, many strains are still resistant for NA, so we should pay attention for fluoroquinolone treatment. Cephalosporin, for example ceftriaxone, tends to cause drug fever, drug eruption and hepatotoxicity as adverse event, and is known its high relapse rate. Furthermore, although it is known that azithromycin resistant strains are spreading, we cannot widely use sensitivity test for azithromycin. For NA resistant and cephalosporin intolerant cases, we think the conventional drugs could be reasonable choice.

1900

HIGH-THROUGHPUT INTEGRATED DISEASE SEROSURVEILLANCE USING A ONESTEP MULTIPLEX BEAD ASSAY

Eric Rogier[1], Gretchen Cooley[1], Sarah Gwyn[1], Heather M. Scobie[1], Kevin Gurrala[1], Delynn M. Moss[1], Vita Cama[1], Guilherme Ogawa[1], Lotus van den Hoogen[2], Chris Drakeley[2], Jean F. Lemoine[3], Diana L. Martin[1], Ventkatachalam Udhayakumar[1]

[1]Centers for Disease Control and Prevention, Atlanta, GA, United States, [2]The London School of Hygiene & Tropical Medicine, London, United Kingdom, [3]Programme National de Contrôle de la Malaria/MSPP, Port-au-Prince, Haiti

Serological data indicating the presence and titer of antibodies against infectious disease and vaccine antigens can provide robust indicators of transmission patterns and immune status in a population. Laboratory testing for large-scale serosurveys is often hindered by time-consuming immunoassays that employ multiple steps for antibody detection and quantification. We present a novel approach to antibody detection by bead-based quantitative immunoassay that involves concurrent incubation with all assay reagents and the sample overnight. When compared to the standard protocol employing tandem incubation steps, this "OneStep" assay protocol was found to amplify the assay signal for IgG detection for 37 of 40 antigens tested from 29 pathogens causing disease in humans. The greatest increases in assay signal were seen at the low- and mid-range IgG titers, and was indicative of an enhancement in the analyte detection, not simply an increase in the background signal of the assay. Upon completion of the OneStep protocol, assay plates stored at 4^0C retained assay signal for up to one month, indicating the stability of the bead complex over time. To compare seroprevalence and immune protection estimates that would be generated for defined study population if using different laboratory protocols or sample types, serum and filter paper blood samples collected during an integrated serosurvey in Haiti were utilized. Estimates for seroprevalence and vaccine-induced protection in the Haiti study population were largely unchanged if different sample types or test protocols were used. This OneStep bead assay protocol has the potential to be applied to various disease group antigens for the high-throughput and timely collection of serosurvey data.

1901

INJURY AS A REASON FOR EMERGENCY DEPARTMENT VISITS IN THE AFTERMATH OF HURRICANE MARÍA IN A SOUTHERN PUERTO RICAN HOSPITAL

Carene A. Oliveras García[1], Laura E. Adams[2], Kyle Ryff[2], Vivian Pérez Gómez[1], Luis Rivera González[1], Wilmer E. Morales Hernández[1], Nicole Irizarry Del Valle[1], Jonathan Figueroa Jiménez[1], Freddie Guzmán Cruz[1], Michelle Surillo González[1], Verónica M. Hurricane María hit Puerto Rico on September 20, 2017. This was the worst documented natural disaster in Puerto Rico's recorded history. Six months after the hurricane, we are still doing reconnaissance as to the extent of damages caused. Within the realm of public health, the aim of our study is to describe the individuals that sought care for injury in the emergency department of a tertiary teaching hospital and its associated urgent care clinic in the aftermath of the hurricane. Using a modified Natural Disaster Morbidity Surveillance Form, we collected the reason for visit of patients that accepted participation after informed consent during the period between October 16, 2017–March 28, 2018. Of the 5,094 participants recruited, 548 (11%) reported injury as the main reason for visit. Of these, 52 (9%) were self-reported to related to the hurricane or rebuilding efforts. The peak of injury cases occurred the week of October 22, 2017 and decreased thereafter. Injured participants had a median age of 52 (range 12–81) years, with 67% male. The most common type of injury in all visits was described as an abrasion, laceration, or cut (45% of all injury visits; 54% of hurricane-related visits). The next most common injury types included sprains/strains (13% of all visits; 10% of hurricane-related visits) and concussions or head injuries (8% of all visits; 13% of hurricane-related visits). The most common mechanism of injury was described as a fall, slip, or trip (268, 49%) or being hit by or against an object (87, 16%). Hurricane-related injury visits were more likely to be associated with being hit by or against an object compared with non-hurricane-related visits (33% to 14%, $p<0.05$) and less likely to be associated with a fall (21% to 52%, $p<0.01$). Most participants with injury-related visits (92%) were discharged to home after evaluation; 3% were admitted to the hospital. This information will be used to better prepare the emergency department in the likely event of a future natural disaster as well as to develop targeted strategies for patient injury prevention.

1902

PREVALENCE OF FLOOD-ASSOCIATED INFECTIOUS DISEASES: A SYSTEMATIC REVIEW AND META-ANALYSIS

Sherief Ghozy[1], Mahmoud Dibas[2], Tarek Turk[3], Sarah Ibrahim Ahmed[4], Mohammad Rashidul Hashan[5], Ghada Mohamed Elhoseny[6], Ahmed Abdelaziz Eisa[7], Tagreed Tarek Abd-elraoof[8], Alaa Alaa El-din[9], Kenji Hirayama[10], Nguyen Tien Huy[11]

Flooding is a natural disaster with major direct and indirect consequences on humans' health. Several studies focused on infectious diseases that increase due to floods. However, none reported the prevalence of post-flood infections and their associated risk factors. Here, we aim to investigate the prevalence of these diseases A comprehensive literature search was performed using nine databases. Data were extracted and results were presented as percentages. We assessed the risk of bias using Cochrane Collaboration's tool. The protocol was registered in PROSPERO (CRD42016043939). Cholera following floods has the highest prevalence among other infections with 47.04%. Leptospirosis showed the widest geographical distribution, overall prevalence (27.72%). Malaria was also frequently reported (13.27%). A wide range of GIT infections were detected as well including bacterial (E-coli, Salmonella, Shigella), viral (Rotavirus) and miscellaneous ones. Skin infections recorder a relatively higher prevalence (23.19%) when compared with respiratory (18.30%), ENT (3%) and ophthalmologic (3.95%) ones. The most frequently reported risk factor is exposure to contaminated water. In Conclusion, several post-flood infections recorded high prevalence including cholera, leptospirosis, malaria and diarrheal infections. Understanding the epidemiological and clinical aspects of these infections can help healthcare responders better anticipate the needs and overcome the challenges that they face during and after floods.

ELECTROCARDIOGRAPHIC FINDINGS IN ADULTS WITH DENGUE FEVER

Walter Taylor[1], Ana Bonell[2], Annette Fox[2], Kinh V. Nguyen[3], Mavuto Mukaka[1], Hoai T. Nguyen[4]

[1]MORU, Bangkok, Thailand, [2]OUCRU, Hanoi, Vietnam, [3]NHTD, Hanoi, Vietnam, [4]Vietnam National Heart Institute, Hanoi, Vietnam

There are few data on the electrocardiographic changes in acute dengue fever. We performed serial 12 lead ECGs (during admission and once at follow up) on adult Vietnamese inpatients with confirmed dengue. A total of 143 (77 males) patients, median (range) age 23.5 (range 16-72) years, were admitted with confirmed dengue on illness days 1-8 (median 5). Only 4 patients had 2007 WHO defined severe dengue. The majority of patients had three ECGs done and the Fridericia corrected QT interval had the least association with the heart rate (adjusted R^2=0.0061, p=0.07). The mean heart rate reached a nadir on D10, mean=64 (95% CI: 60.6-67.4)/min, the same day as the peak QTcF: 401 (392 - 410) msec. These nadir and peak times occurred later than the days of nadir platelet count (D5) and the peak haematocrit (D4). No patient had an uncorrected QT exceeding 500 ms and 1 patient had a QTcF of 501 msec. Three females and 8 males had QTcF values exceeding the upper limit of normal (ULN) of 450 and 430 ms, respectively. The proportions of patients with bradycardia (heart rate less than 60/min) rose from 1/12 (8.3%) on D4, peaked at 9/34 (26.5%) on D10 and fell to 3/19 (15.8%) on D30. The mean PR interval (150 ms) changed little over time and 4 patients had 7 episodes of an increased PR interval. By mixed effects modelling for repeated measures, only temperature was a significant explanatory variable. Most ECG parameters were within the normal range. These QTcF values represent the natural QTcF variability in nonsevere dengue.

1904

A SIX YEAR REVIEW COMPARISON PROFILES OF INFECTIOUS DISEASES IN UNDER-NOURISHED AND WELL-NOURISHED CHILDREN IN RURAL SUB-SAHARAN AFRICA PRIMARY CARE CENTER

Yorro Bah, Fatai Momodu Akemokwe, Abdoulie Faal, Ousman Bajinka

Medical Research Council Unit The Gambia at London School of Hygiene & Tropical Medicine, Banjul, Gambia

This study aimed to compare pattern of infectious diseases recorded in malnourished children compared to well-nourished children in a free rural primary care clinic in Kiang West District The Gambia.The interrelated nature of the occurrence of infectious diseases amongst malnourished and well-nourished children is still among the topics that need a thorough research. Severe acute malnutrition (SAM) and moderate acute malnutrition (MAM) are associated with increased severity of common infectious diseases. Death amongst children with severe acute malnutrition is almost always as a result of infection. Malnutrition is common in Kiang West District particularly during the "hunger" season from the month of August to October every year. We retrospectively analysed data from the Keneba Electronic Medical Records System looking for records of all children 5 years and below seen with ICD-10 codes for various prevalent of infectious diseases between January 2010 and December 2017. Data of children with normal anthropometry characteristics was compared against those with moderate acute malnutrition (WHO z score -2 to -3) and severe acute malnutrition (WHO z score greater than -3). Both moderate acute malnutrition and severe acute malnutrition were compared against each other and in reference to the well-nourished children. Common colds were the most prevalent infectious diseases in all groups followed by pneumonia. Overall, all infectious diseases diagnosed apart from common colds, intestinal helminthiasis and acute otitis media were more common among malnourished children compared to well-nourished children. There was an increasing gradient in relative frequency of pneumonia, HIV, septicaemia, UTIs, malaria, giardiasis and tuberculosis from well-nourished through moderate acute malnutrition to severe acute malnutrition. The relative frequency of prevalent infectious diseases among children of age 5 years and below in this study differed by their state of nutrition. More severe forms of infectious diseases occurred more frequently with worsening malnutrition in children 5 years and below in Kiang West District.

1905

THE LAST STEP BEFORE STOPPING TRACHOMA MDAS IN CAMEROON

Assumpta L. Bella[1], Georges Nko'Ayissi[1], Julie Akame[2], Patrick Mbia[2], Yaobi Zhang[3], Steven Reid[4], Emilienne Epee[1]

[1]Ministry of Public Health, Yaounde, Cameroon, [2]Helen Keller International, Yaounde, Cameroon, [3]Helen Keller International, Regional Office for Africa, Dakar, Senegal, [4]Helen Keller International, New York, NY, United States

Cameroon is on the brink of eliminating trachoma as a public health problem by 2020. Initial mapping in 54 health districts (HDs) showed that 5 HDs were not endemic (trachomatous inflammation - follicular (TF)

0%), 28 HDs had TF≤5%, 5 HDs had a TF prevalence of 5-9.9% and the remaining 16 HDs had TF ≥10%. Mass drug administration (MDA) started in the 16 HDs with the highest TF prevalence followed by the 5 HDs with TF 5-9.9. In 2016, 7 HDs (out of 21) met the criteria to stop MDA as trachoma impact survey (TIS) showed TF <5%. In 2017 the other 14 HDs carried out TIS with funding from USAID/RTI. This abstract presents the findings of the last TIS to be performed in Cameroon. The TIS were carried out via a cross-sectional study based on a stratified random sampling. In each of these HDs, 30 communities each representing a cluster were selected; then, 30 households were selected in each community. Each team included a grader and a recorder, and all teams were provided with training before field data collection. Data were collected using android smartphones and transferred to a Tropical Data (TD) platform. These data were analyzed by both National Program staff and the TD Data Manager. Overall 390 communities were surveyed, 30 communities per HD. Teams visited 11,664 households and they examined 54,947 people. In all the surveyed HDs, the number children aged 1-9 years who were examined reached the sample threshold required for a valid TF estimate. In the surveyed HDs, the prevalence of TF in children aged 1-9 years varied from 0% to 2.5% (CI: 2.3-2.7). All these prevalence are below the endemic threshold of 5%. The decrease of the TF prevalence in these 14 HDs after effective MDA rounds demonstrates the efficacy of the «A» component (from the SAFE strategy) as well as the effectiveness of its implementation. These results from this last group of eligible HDs indicate National Program can stop MDA in these HDs, meaning that trachoma MDA is no longer required in Cameroon. However, to maintain the TF prevalence below the endemic threshold, the country should continue to implement the "F" and the "E" components from the SAFE strategy.

1906

CHARACTERIZING UNDERNUTRITION AMONG INFANTS AGED 1 TO 6 MONTHS IN HIGH MORTALITY AFRICAN SITES WITHIN THE CHILD HEALTH AND MORTALITY PREVENTION SURVEILLANCE (CHAMPS) NETWORK

Jessica H. Watson[1], Amanda L. Wilkinson[1], Rebecca P. Philipsborn[2], Quique Bassat[3], Peter N. Onyango[4], Shabir A. Madhi[5], Richard Chawana[5], Dianna M. Blau[1], Pratima L. Raghunathan[1], Robert F. Breiman for the CHAMPS Network[2]

[1]Centers for Disease Control and Prevention, Atlanta, GA, United States, [2]Emory Global Health Institute, Atlanta, GA, United States, [3]Barcelona Institute for Global Health, Barcelona, Spain, [4]Kenya Medical Research Institute / Centers for Disease Control and Prevention, Kisumu, Kenya, [5]Respiratory and Meningeal Pathogens Research Unit, University of Witwatersrand, Johannesburg, South Africa

Globally, an estimated 3.8 million infants <6 months (U6M) are severely wasted. However, analyses often exclude infants U6M, as no consensus exists on reliable undernutrition indicators in this age group. Anthropometric measurements in infants U6M may reflect gestational age (GA), intrauterine factors, or postnatal nutritional status. Growth standards for preterm infants exist but rely on accurate assessment of GA, which is lacking in many settings. The Child Health and Mortality Prevention Surveillance (CHAMPS) Network aims to improve understanding of child mortality in high-burden settings. We aimed to create a standard approach to identify undernutrition in deceased CHAMPS cases 28 days to U6M and compare different assessment methods. We applied CHAMPS postmortem measurements to three indicators of undernutrition: severe underweight (weight-for-age z-score <-3) based on WHO Child Growth Standards (WHO-GS); severe underweight based on INTERGROWTH-21st Newborn Size Standards (IG-NS), which account for GA; and severe acute malnutrition (SAM) based on mid-upper arm circumference (MUAC) <11cm. Of 84 CHAMPS cases 28 days to U6M, only those with GA available from clinical records (n=36) or with GA unavailable but birthweight ≥2500g (n=6; considered term for analysis) were included. Of the 42 cases, 64% were preterm (GA <37 weeks). The proportion of cases with severe underweight was 74% (n=31) according to WHO-GS and 50% (n=21) according to IG-NS. Among the 27 preterm infants, WHO-GS classified 89% as severely underweight whereas IG-NS classified 52%. Based on MUAC, 74% of all cases and 82% of preterm cases had SAM. By accounting for GA in cases 28 days to U6M, IG-NS likely generated a more reliable estimate of the true undernutrition burden and resulted in a 32% decrease in cases with severe undernutrition compared to WHO-GS or MUAC. Overall, all three methods suggest severe undernutrition is common in this population. With increasing survival of premature infants, standardized anthropometric indicators in infants U6M are needed towards reliably characterizing undernutrition when GA is unknown.

1907

ALTERNATIVE STRATEGY FOR THE DEWORMING OF SCHOOL-AGED CHILDREN IN THE NORTHWEST AND THE SOUTHWEST REGIONS OF CAMEROON IN AN INSECURE SOCIO-POLITICAL CONTEXT

Victor Mbome Njie[1], Manjo Mathilda[1], Tchuem Tchuente[1], Joseph Oye[2], Serge Akongo[2], Julie Akame[3], Patrick Mbia[3], Carine Fokam[3], Michel Hendji[3], Yaobi Zhang[4], Steven Reid[5]

[1]Ministry of Public Health, Yaounde, Cameroon, [2]Sightsavers, Yaounde, Cameroon, [3]Helen Keller International, Yaounde, Cameroon, [4]Helen Keller International, Regional Office for Africa, Dakar, Senegal, [5]Helen Keller International, New York, NY, United States

The Cameroon NTD program carries out mass drug administration (MDA) for soil-transmitted helminths (STH) and schistosomiasis (SCH) with mebendazole (MEB) and praziquantel (PZQ) respectively, to school aged children (SAC) aged 6-14 regardless if they are enrolled. In 2017, a teachers' strike and socio-political unrest in the South-West and North-West regions led to the cessation of school classes. Consequently, the planned school-based deworming activities could not take place in schools. The South-West and North-West regions have 18 and 20 health districts (HD) respectively. Both are endemic with STH and 12 HDs are endemic with SCH. To ensure continuity of treatment, the health authorities along with Sightsavers, adopted a community-based distribution as an alternative deworming strategy. MDA was carried out using a door-to-door method and supervision was provided as well as data monitoring during the MDA. The regions were able to mobilize additional funds, increasing the initial global grant by 35%. 2570 community drug distributors (CDDs) were provided with training in the North-West and 2399 in the South-West region. Importantly, the therapeutic coverage reached 85% for MBD and 86.9% for praziquantel PZQ)in the North-west, and 87% for MBD and 84% for PZQ in the South-West. These results show that the community-based approach is an effective alternative to the school-based approach. The advantages of this strategy include allowing the CDDs to reach out-of-school children normally difficult to reach through the school-based strategy. It also reduced data reporting delays and it allowed strengthening capacity though health system pyramid including communities. Moreover, the therapeutic coverages were improved using this strategy than have been achieved in the last two years: (South-West: 50.93% for MBD, 49.10% for PZQ - North-West: 96% for MBD, 73% for PZQ) and in 2016 (South-West: 51.58% for MBD, 53.34% for PZQ - North West: 89.6% for MBD, 66.17% for PZQ). Despite these improvements it must be noted that the community based approach is more expensive and it should be accompanied by quality assurance mechanisms.

1908

SCREENING FAILURES: HOW TO IMPROVE COVERAGE OF VACCINATION

Antonio E. Sama[1], Vicente Urbano[2], Esther Eburi[1], Stephen Manock[3], Carl Maas[4], Carlos Cortes[1], Matilde Riloha[2], Stephen L. Hoffman[3], Salim Abdullah[5]

[1]MCDI, Malabo, Equatorial Guinea, [2]MINSBS, Malabo, Equatorial Guinea, [3]Sanaria, Maryland, MD, United States, [4]Marathon Oil, Malabo, Equatorial Guinea, [5]IHI, Bagamoyo, United Republic of Tanzania

Evaluation of the PfSPZ vaccine has been conducted in Equatorial Guinea (EG) since 2015. A Phase I and a Phase II trial has been completed. Currently preparations are ongoing to conduct a Phase II and Phase III trial in EG. As part of the preparatory activities an assessment will be done on the proportion and profile of potential trial subjects excluded from enrolment based on inclusion and exclusion criteria set for the two trials. The potential participants of the two trials will be invited for screening and detailed information about health history and social background will be collected. Physical examination will be done and blood samples collected for laboratory analysis. Based on the protocol guidelines and eligibility criteria eligible will be invited for enrollment. Participants excluded prior to any vaccination are considered as "screening failures" and the reasons for their exclusion are various. Data from the screening failures will be analyzed in comparison to those enrolled and the total number of screened participants to gain insight on the contributing factors for non-participation for individuals who consider themselves healthy in the community. The proportions of screening failures will be calculated and categorized with respect to age group and reason(s) for exclusion. These will be extrapolated to get an estimate of how many people on the Island of Bioko would potentially *not be* eligible for future biomedical research like a vaccine study. The implication of the screening failures on the logistics of the conduct of the trials and potential options for optimizing recruitment for the trials or any additional supportive measures will be discussed.

1909

A POST MASS DRUG ADMINISTRATION COVERAGE EVALUATION AND KNOWLEDGE, ATTITUDES AND PRACTICES SURVEY IN TWO HEALTH DISTRICTS IN MALI

Mahamadou Traoré[1], Boubacar Guindo[2], Mama Nielé Doumbia[2], Issa Yalcouyé[3], Harouna Ninag[4], Seydou Goita[2], Modibo Keita[2], Massitan Dembélé[1], Abdoulaye Guindo[1], Abdoul Karim Sidibé[1], Steven Reid[5], Mohamed Lamine Yattara[2], Marily Knieriemen[2], Benoit Dembele[2], Yaobi Zhang[6]

[1]Ministère de la Santé et de l'Hygiène Publique/ Direction Nationale de la Santé, Bamako, Mali, [2]Helen Keller International, Bamako, Mali, [3]Ministère de la Santé et de l'Hygiène Publique/ Direction Nationale de la Santé, Ségou, Mali, [4]Ministère de la Santé et de l'Hygiène Publique/ Direction Nationale de la Santé, Mopti, Mali, [5]Helen Keller International, New York, NY, United States, [6]Helen Keller International, Regional Office for Africa, Dakar, Senegal

Mali has implemented preventive chemotherapy for neglected tropical diseases (NTDs) for the last 10 years. A post mass drug administration (MDA) coverage survey was conducted in Bandiagara and Barouéli health districts (HDs) in July 2017 as difficulties in achieving sufficient coverage had been reported. The MDA for schistosomiasis (SCH) and soil-transmitted helminths (STH) was conducted with both a school-based and community strategy (school enrolment rate is around 50%) targeting school-aged children (SAC). Sampling was done using the WHO protocol with probability proportional to estimated size with segmentation "PPES-Segmentation" methodology and the Coverage Survey Builder. The target population for the survey was SAC as they were the targets of the MDA. Data were captured electronically. A total of 3,500 SAC were recruited for the survey: 1,637 in Bandiagara and 1,863 in Barouéli HDs. The survey showed that, using SAC as the denominator, 96.2% (1,605/1,637) in Bandiagara and 86.2% (1,575/1,863) of SAC in Barouéli received drugs, while 96.1% (1,573/1,637) in Bandiagara and 85.7% (1597/1863) in Barouéli reported taking the drugs (swallowing). 320 SAC did not receive drugs during the MDA (62 and 258 SAC in Bandiagara and Barouéli, respectively). The main reasons cited were: unaware of the MDA, 30.9% (99/320); the community drug distributors (CDDs) did not come to their home, school or public place, 24.4% (78/320) and absence from the home during the MDA 21.3% (68/320). Side- effects were reported by 14% of surveyed children (<1% were moderate - interfered with daily activities) and there were no serious adverse events. SAC were informed about the MDA by CDDs, family members, community leaders and community radios. These results show that the surveyed coverage rates were lower than those reported: 103.9% in Bandiagara and 100.1% in Barouéli during the MDA, but were still above the minimum threshold of 75% recommended by WHO. These results also indicate that a combined school and community based MDA strategy is effective in Mali for SCH and STH MDA.

1910

TRACHOMA SITUATION IN 2017 ONE YEAR BEFORE ELIMINATION DATE IN MALI

Lamine Traoré[1], Modibo Keita[2], Benoit Dembele[2], Famolo Coulibaly[1], Mamadou Dembele[1], Dramane Traore[2], Brehima Mariko[1], Seydou Goita[2], Abdoul Karim Sidibé[1], Steven Reid[3], Fama Kondo[2], Mama Nielé Doumbia[2], Mohamed Lamine Yattara[2], Marily Knieriemen[2], Yaobi Zhang[4]

[1]Ministère de la Santé et de l'Hygiène Publique, Bamako, Mali, [2]Helen Keller International, Bamako, Mali, [3]Helen Keller International, New York, NY, United States, [4]Helen Keller International, Regional Office for Africa, Dakar, Senegal

Mali has implemented the World Health Organization's SAFE strategy for trachoma elimination since 1997 and has committed to eliminating trachoma as a public health problem in 2018. Trachoma mapping conducted in 1996/1997 showed that all regions in Mali were endemic. The prevalence of trachomatous inflammation-follicular (TF) in children under 10 years of age ranged from 23.1% to 46.7% and that of trachomatous trichiasis (TT) in women over 14 years of age ranged from 0.65% to 3.9%. Based on the results of the mapping, the backlog of patients requiring TT surgery was estimated at 85,000 adults. Mass drug administration (MDA) was conducted in endemic health districts (HDs) from 2002 to 2016 and mass TT surgery started in 1999. In addition, radio messages focused on trachoma prevention have been widely broadcasted and slabs for latrines provided to some households in high TF prevalence areas. The objective of this study is to describe the current trachoma situation in Mali one year before the planned elimination date. The study evaluated the results of the SAFE strategy implemented from 1997 to 2017 as shown by results from impact and surveillance surveys conducted according to WHO guidelines. The TT surgical backlog was revised each year based on results of TT prevalence surveys and the number of patients operated. At the end of 2017, all 66 of Mali's HDs endemic for TF at baseline have achieved the elimination threshold (<5% in children 1 - 9 years of age). The threshold of TT elimination (<0.1% all ages) was reached in 48 of 57 HDs originally endemic for TT. The backlog of people requiring TT surgery has decreased by 93% (from 85,000 to 5,893) and is now located in only 9 of the 57 HDs. Based on these results, Mali is poised to eliminate trachoma as a public health problem by the end of 2018. The country must now complete the pre-validation surveys (including in some insecure areas), conduct surgery to eliminate the TT backlog, and prepare the trachoma elimination dossier for WHO.

1911

MONOCYTE SUBSETS AND CO-STIMULATORY MOLECULES IN LEPROSY REACTIONS

Paulo R. Machado, Mayume Shibuya, Giovana Bergheme, Sara Passos, Jamile Rêgo, Lucas P. Carvalho

Federal University of Bahia, Salvador, Brazil

Leprosy reactions are acute inflammatory events associated with several clinical manifestations leading to disabilities and permanent deformities due to peripheral nerve damage. Type 1 reactions are the main cause of neuritis, whereas type 2 reactions are characterized by systemic involvement and symptoms like fever, arthritis, myalgia, neuritis and erythema nodosum. Understanding host immune pathways associated with tissue damage during reactions are of upmost importance to the development of immune intervention strategies in order to develop better treatment or prevention. The participation of monocytes in leprosy reactions was evaluated by determining the frequency of monocyte subsets and the degree of cellular activation through the expression of MHCII and the co-stimulatory molecules CD40, CD80, CD86. Leprosy subjects with or without reactions were included in this cross-sectional study. Peripheral blood mononuclear cell were isolated and stained *ex-vivo* to determine monocyte subsets and the degree of cellular activation by flow cytometry. Intermediate monocytes were increased in leprosy patients with reactions when compared to patients without reactions. Although no difference was detected in the frequency of monocyte subsets between type 1 and 2 reactions, the expression of CD80 was increased in monocytes from patients with type 1 reactions and CD40 was higher in PB subjects presenting type 1 reactions. Moreover, CD86 and MHC II expression were higher in intermediate monocytes when compared to the other subsets in leprosy reaction types 1 and 2. Our data indicates that intermediate monocyte activation with CD86 and MHCII expression is involved with both type 1 and 2 reactions, whereas CD80 and CD40 expression is related to type 1 reactions.

1912

A CROSS-SECTIONAL STUDY OF HEMATOLOGIC AND INFECTIOUS MORBIDITY IN KENYAN CHILDREN WITH SICKLE CELL ANEMIA

Sarah A. Korwa[1], Joseph K. Kirui[1], Casey Silver[2], Sheila Clapp[3], Wendy P. O'Meara[4], Festus Njuguna[1], Steve M. Taylor[2]

[1]Moi University, Eldoret, Kenya, [2]Duke University, Durham, NC, United States, [3]Duke Clinical Research Institute, Durham, NC, United States, [4]Duke Global Health Institute, Durham, NC, United States

Sickle cell anemia (SCA) afflicts over 200,000 newborns annually in sub-Saharan Africa, where it is highly prevalent in malaria-endemic areas. In these settings, it causes early childhood deaths owing to infectious and hematologic complications. To mitigate these risks, supportive care for children with SCA typically entails measures to directly prevent infections and anemia and indirectly prevent painful crises, delayed development, hospitalizations, and death. In Kenya, SCA is common in children in malarious regions bordering Lake Victoria, but the burden of SCA complications is poorly understood in these populations. We measured infectious, hematologic, and functional complications in children with SCA who were enrolling in a clinical trial of malaria chemoprevention regimens in Homa Bay, Kenya. Participants were enrolled if they were 1y-10y, had hemoglobin SS disease confirmed by electrophoresis, and lacked ongoing chronic medical conditions that would interact with trial procedures. From January 2018, we enrolled over 150 participants meeting these criteria and conducted comprehensive medical and social histories, reviews of systems, physical exams, electrocardiograms, splenic ultrasounds, blood counts and electrolyte measures, and testing for malaria parasites. Our study confirms the Kenyan children with SCA have high burdens of multi-system morbidity. This group of children with poor health outcomes in tropical settings requires focused exploratory, comparative, and implementation studies in order to prolong their survival and enhance their healthspan.

1913

EMERGENCY VISITS TO A HOSPITAL SYSTEM IN SOUTHERN PUERTO RICO IN THE AFTERMATH OF HURRICANE MARIA

Veronica M. Frasqueri[1], Xiomara Torres[1], Luzeida Vargas[1], Laura E. Adams[2], Nicole M. Perez-Rodriguez[1], Angel L. Perez[1], Kyle Ryff[2], Liliana Sanchez-Gonzalez[2], Gabriela Paz-Bailey[2], Luisa I. Alvarado[1]

[1]Ponce Health Sciences University, Ponce, Puerto Rico, [2]Centers for Disease Control and Prevention, San Juan, Puerto Rico

During September 2017, Hurricane Maria, a category 4 storm, made landfall in Puerto Rico. This event created an environment with countless health hazards, increasing the risk of injuries, wound infections, communicable diseases, and complications of chronic illnesses and mental illnesses. In the aftermath of this natural disaster, the Sentinel Enhanced Dengue Surveillance System (SEDSS) established a syndromic surveillance study on October 2017 at the emergency department of a tertiary care teaching hospital and associated urgent care clinic located in the southern area of the island. A modified CDC's Natural Disaster Morbidity Surveillance Form was used to collect the occurrence of injuries and illnesses and detect outbreaks during a disaster. We offered enrollment to all patients who presented to the emergency department or urgent care clinic during the staff coverage period from October 16, 2017 to March 28, 2018. After obtaining informed consent, surveillance personnel interviewed participants briefly to categorize their reason for visit and later obtain outcomes through the electronic medical record. A total of 5,116 participants were enrolled; 1,405 (27.5%) were between the ages of 1-18 and more than half of them (51.0%) were male. One hundred (2.0%) respondents reported the visit as a result of disaster work or response activities. The most common reason for visit was acute illness (78.8%) and 570 (11.1%) of study participants were hospitalized. Among the participants, 13 had a Leptospirosis rapid test performed, of which 4 (30.8%) were positive cases. In addition, 1,487 Influenza rapid test were performed and 392 (26.4%) resulted positive. Active post-event morbidity surveillance provides a quickly scalable model to provide decision makers with actionable information following a disaster that may reduce mortality and morbidity. Furthermore, the information gathered through this surveillance can be used for developing disaster ready public health systems and educational campaigns to better address the immediate needs of those affected by future natural disasters, such as hurricanes.

1914

SCHISTOSOMIASIS AND SOIL-TRANSMITTED HELMINTHS CONTROL IN SCHOOL-AGED CHILDREN IN NIGER

Issa Gnandou[1], Issoufou Mounkaila[2], Youssouf Yaye[2], Tourawa Ramatou[1], Amadou Sahadatou[1], Abdoulaye Mariama[1], Amy Vienoglou[3]

[1]Ministry of Health, Niamey, Niger, [2]Helen Keller International, Niamey, Niger, [3]Helen Keller International, New York, NY, United States

Worldwide, about 1.5 billion people are infected with soil-transmitted helminths (STH) and 206 million people require treatment for schistosomiasis (SCH). In Niger, 69% of the population was found to be infected with STH or SCH in 1995, and in 2004, the National Program for the Control of SCH and STH was established. In 2006, Niger drew up a national plan for the integrated control of neglected tropical diseases (NTDs), one of the objectives of which was to reduce the morbidity caused by SCH and STH. Deworming for SCH and STH began in 2004 and was integrated into national scale mass drug administration (MDA) for NTDs in 2007. Districts have received between four and ten rounds of treatment with praziquantel and albendazole. In 2016, a cross-sectional sentinel site survey was conducted to determine SCH and STH prevalence in school-aged children after years of mass treatment. Sixty children aged from 6 to 8 years from each of 17 sentinel sites (schools) were selected and urine and stool samples were examined through urinary filtration and the Kato Katz techniques. Among the 1,020 children examined, the overall average prevalence of SCH was 33.5% (95% confidence interval [CI]: 19.2%-

47.9%), ranging from 1.7% in Filingue to 100% in Tera among districts. This was a 52.3% reduction from the 2011 surveys which showed an average prevalence of 70.2% (95% CI: 63.6%-76.8%), ranging from 44% to 96% among districts. Three types of intestinal worms were reported: Ascaris lumbricoides, Trichuris trichiura and Ancylostoma duodenale. The overall average STH prevalence was 6.8% (95% CI: 4.0%-9.5%), ranging from 0% to 20% among districts. After several rounds of treatment, there was a marked decrease in the prevalence of urogenital schistosomiasis, except for Yelwani, Boudoum, Doungouram, and Bangoukoukou sites. STH prevalence is generally low with 8 of 17 sites with a prevalence <5%. Multiple rounds of MDA and sensitization on hygiene and sanitation all appear to contribute to reduced SCH and STH in these sites.

1915

INAPPROPRIATE ANTIBIOTIC PROVISION FOR DIARRHEA AMONG HEALTH PROVIDERS IN RURAL MALI

Emily Treleaven[1], Jenny Liu[2], Eric Schatzkin[2], Caroline Whidden[3], Nancy Padian[4], Souleymane Cissouma[5], Yacouba Samake[3], Youssouf Keita[3], Djoumé Diakite[3], Mohamed Traore[3], Naïmatou Kone[3], Ari Johnson[3], Kassoum Kayentao[6]

[1]University of Michigan, Ann Arbor, MI, United States, [2]University of California San Francisco, San Francisco, CA, United States, [3]Muso, Bamako, Mali, [4]University of California Berkeley, Berkeley, CA, United States, [5]Ministry of Health, Bamako, Mali, [6]Malaria Research and Training Center, Bamako, Mali

Clinically inappropriate provision of antibiotics is of growing global concern given the recent rise in antibiotic resistance. However, the dynamics of antibiotic provision for pediatric illnesses in West Africa are not well understood. From December 2016 to February 2017, mothers of 19,556 children under age five were interviewed in a baseline household survey for a cluster-randomized trial across seven health catchment areas in rural Mali. Respondents provided information about whether children experienced diarrhea with or without bloody stools in the two weeks preceding the survey, care sought, and treatment received. We used mixed-effects regression models to assess predictors of receipt of antibiotics for children reporting recent diarrheal illness without bloody stools by patient characteristics (distance to facility, child age and sex, household wealth, and maternal education) and provider characteristics (sector, facility type, catchment area). Among 2,136 children with diarrheal illness (no bloody stools), 45.9% sought any care outside the home, 26.7% of whom received inappropriate antibiotic treatment versus oral rehydration therapy (ORT) and zinc. Provision of antibiotics for diarrheal illness is concentrated among trained providers: 45.2% of children attending a hospital, primary health facility, or community health worker received antibiotics versus 15.3% who attended untrained providers ($p<0.001$). Inappropriate antibiotic provision rates were higher than provision rates of ORT and zinc across sectors. There was no difference in cost of treatment among children who received incorrect antibiotics versus those who received ORT and zinc. We find no effect of distance to facility or socio-demographic characteristics on likelihood of antibiotic receipt for diarrheal illness. Given that trained providers are significantly more likely to prescribe antibiotics for diarrheal illness without bloody stools than untrained providers, and to provide antibiotics more frequently than ORS and zinc, our findings suggest better antibiotic stewardship and remedial training for trained providers are needed.

1916

A POST MASS DRUG ADMINISTRATION COVERAGE SURVEY FOR TRACHOMA TREATMENT IN GUINEA

André Géopogui[1], Christelly Badila Flore[2], Mamadou Siradiou Baldé[1], Cece Nieba[1], Brian Fuller[3], Jean Jacques Ngamaleu Tougoue[3], Lamah Lamine[2], Bamba Foungotin Ibrahim[2]

[1]Ministry of Health, Conakry, Guinea, [2]Helen Keller International, Conakry, Guinea, [3]RTI International, Washington, DC, United States

Mass drug administration (MDA) for trachoma started in Guinea in 2013. Treatment coverage has always been reported as reaching 80% or more except in 2014 when coverage was below 80% due to the outbreak of Ebola virus disease. With the use of the new population census in 2016, underestimations of population were reported in the majority of health districts (HDs) treated. The national program carried out a post-MDA coverage survey to confirm the high reported coverage rates. A cross-sectional survey using a cluster sample design was conducted in July 2017 in randomly selected areas in 4 health districts (HD) in Guinea to validate the administrative coverage obtained during the trachoma MDA undertaken in May 2017. In each district, the sample size was calculated using the Coverage Survey Builder (CSB) tool. Survey households were selected using the segmentation method recommended by WHO. All individuals in selected households were presented with a drug sample and asked about taking the drug during the campaign. Data were collected electronically using an Android device via Open Data Kit (ODK) application. Survey coverage was then compared with administrative coverage. A total of 1,249 households were surveyed, of which, 1,243 (99.5% agreed to participate in the survey). A total of 7,901 (3,776 males and 4,125 females) individuals were present, of which 5,121 adults and 2,780 children under 10 years of age. The survey coverage varied from 78.6% (95%CI: 76.5 - 80.4%) to 96.7% (95%CI: 95.9 - 97.4%) where one of the four surveyed HD reported insufficient coverage below 80%. The survey coverage results revealed a significant difference between reported coverage and survey coverage: From 96.3% to 78.6% in Boffa, from 94.8% to 88.3% in Forécariah, from 90.4% to 96.7% in Kissidougou and from 88.7% to 82.1% in Kouroussa. Even though reported coverages were not validated by the survey coverage, all survey coverages were greater than 80% in all HDs except in Boffa. The reasons for this low coverage below 80% in Boffa should be investigated to ensure sufficient coverage will be achieved in future MDAs.

1917

TORCH SEROPREVALENCE IN PREGNANT WOMEN FROM PERI-URBAN IQUITOS IN THE AMAZON JUNGLE OF PERU

Luis Cabrera-Sosa[1], **David Durand**[1], Anika Eca[1], Nohelia Gamboa[2], Jorge Parraguez[2], Martín Casapía[2], Cesar Ugarte-Gil[1], David Kimberlin[3], Theresa J. Ochoa[1]

[1]Instituto de Medicina Tropical "Alexander von Humboldt", Universidad Peruana Cayetano Heredia, Lima, Peru, [2]Asociación Civil Selva Amazónica, Iquitos, Peru, [3]School of Medicine, University of Alabama, Birmingham, AL, United States

Some infections acquired during pregnancy can be transmitted to the infant causing abnormal development. These infections include toxoplasmosis, rubella, cytomegalovirus (CMV), herpes simplex (HSV) and others (TORCH). As part of clinical care in Peru, it is mandatory to test for syphilis and HIV during pregnancy; however, there is no routine testing for the TORCH infections listed above. As a part of a prospective, international, multisite cohort study of the incidence and outcomes on Zika virus infection during pregnancy (ZIP study), 350 pregnant women have been enrolled in their first or early second trimester from peri-urban communities in Iquitos, Peru. Blood samples have been collected at enrollment to test for syphilis, HIV and TORCH. We determined the seroprevalence of toxoplasmosis, CMV, rubella, and HSV in 244 women using a commercial ELISA for IgM. The mean age of the women enrolled was 26 ± 6.6 years, the gestational age at sample collection was 13.1 ±

3.2 weeks, and 30% were primigravida. One (0.4%) sample was positive for syphilis and 3 (1.2%) for HIV. Sixteen (6.6%) samples were positive for *Toxoplasma gondii*, 54 (22.1%) for CMV, 12 (4.9%) for rubella, and 75 (30.7%) for HSV 1 or 2. In addition, 9 (3.7%) women had equivocal results for toxoplasmosis, 14 (5.7%) for CMV, 5 (2%) for rubella, and 20 (8.2%) for HSV 1-2. All equivocal samples are being retested. Almost half of the women (107, 43.9%) had negative IgM for all TORCH infections, and only one (0.4%) was positive of all. The most frequent profile was a IgM positive only for HSV (37, 12.5%) and only for CMV (20, 8.2%). Although these results need to be confirmed with additional testing (e.i. IgG avidity test for toxoplasma), the high IgM seroprevalence of TORCH infections found in this study provides evidence to support local routine testing during pregnancy by the Ministry of Health. In addition, in order to maintain the elimination of congenital rubella in the region, it is important to strive for high immunization rates with MMR (measles, mumps and rubella).

1918

IDENTIFICATION OF BARRIERS TO HYDROCELE SURGERY: CASE STUDY OF THE BIREME AND KARA-HAY HEALTH DISTRICTS IN CAMEROON

Biholong Benjamin[1], Julie Akame[2], Yannick Nkoumou[2], Michel Hendji[2], Zeina Sifri[3], Stephanie Parker[3], Medesse Sonou[3], Whitney Goldman[3], Stefania Slabyj[3], Emily Gower[4]

[1]Ministry of Public Health, Yaounde, Cameroon, [2]Helen Keller International, Yaounde, Cameroon, [3]Helen Keller International, New York, NY, United States, [4]University of North Carolina, Chapel Hill, NC, United States

In 2017, the USAID-funded Morbidity Management and Disability Prevention (MMDP) Project supported the Cameroon Ministry of Health to conduct a pilot project for the management of lymphatic filariasis-related morbidity cases in five health districts of Cameroon. As a part of this effort, a study to identify patient-reported barriers to hydrocele surgery was conducted in two health districts (Bireme and Kara-Hay). From 405 suspected cases of hydroceles identified in Bireme and Kara-Hay districts, a convenience sample of 86 patients was selected from the four health areas in each health district that reported the highest number of suspected cases, for a total of eight health areas selected. Data was collected using a standard questionnaire asking about knowledge of health facilities providing hydrocele surgery, means of transportation to these facilities, and initial thoughts on the costs and other factors that could influence the decision to have surgery. Less than one third of the respondents (27 of 86, or 31%) said they were able to afford the cost of surgery. Of the remaining 59 respondents, 44 reported that they would be able to cover indirect surgery costs (e.g., transportation, food), and 15 reported being unable to support any direct or indirect costs. Fear of surgery and of adverse effects after surgery were also identified as potential obstacles. Specifically, 4% of respondents feared the possibility of erectile dysfunction following surgery, 1% feared not being able to wake up following general anesthesia, and 1% were afraid sterility following surgery. These results highlight cost as a major obstacle to hydrocele surgery and underline the importance of considering universal health coverage or subsidies for essential surgeries such as hydrocele surgery. Fears raised by patients, though cited less frequently than cost, will also be an important obstacle to address through the development of behavior change communication strategies.

1919

STRENGTHENING THE QUALITY OF TRACHOMATOUS TRICHIASIS SURGICAL SERVICES: USING AN INTEGRATED SUPPORTIVE SUPERVISION APPROACH

Sabrina LaTorre[1], Yannick Nkoumou[2], Issouf Bamba[3], Whitney Goldman[4], Medesse Sonou[4], Emily Gower[5], Zeina Sifri[4], Stephanie Parker[4], Stefania Slabyj[4]

[1]Helen Keller International, Dakar, Senegal, [2]Helen Keller International, Yaounde, Cameroon, [3]Helen Keller International, Ouagadougou, Burkina Faso, [4]Helen Keller International, New York, NY, United States, [5]University of North Carolina, Chapel Hill, NC, United States

Supportive supervision is critical to ensuring quality of trachomatous trichiasis (TT) surgery interventions, impacting both productivity and quality of surgery. The USAID-funded Morbidity Management and Disability Prevention (MMDP) Project has supported national trachoma programs to strengthen supportive supervision and train national TT surgeon supervisors in project-supported areas. A key component of the approach was the development of a supportive supervision checklist for both general and technical aspects of TT management service provision. The general checklist can be completed by non-technical staff trained in preferred practices who assess social mobilization, patient counseling, infection control and health care waste management. The technical component must be assessed by surgeons trained specifically as supervisors who assess pre-, peri- and post-operative procedures. The checklists have been implemented in three countries in areas supported by the project, each with very different disease burdens. As few as three or as many as 128 individual surgeons or surgical teams operate in project-supported areas and, therefore, require supportive supervision. To date, between 30% and 100% of these surgeons or teams have received technical supportive supervision visits, with the proportion naturally highest in areas with fewer surgeons or teams operating. Supportive supervision enables close monitoring of TT surgeon performance. The approach has identified high performing surgeons who have been trained as supervisors, and provides the opportunity to triangulate findings with 3-6 months post-operative outcome data for operating surgeons. In 2018, the curriculum for a refresher training for operating surgeons in Cameroon was tailored to focus on findings reported through supportive supervision and 3-6 month outcome data. Given the utility and feasibility of integrating supportive supervision into the project-supported areas, this experience supports introduction of these activities as a routine component of TT management services for program strengthening.

1920

MALARIA AND VIRAL INFECTIONS OF THE UPPER RESPIRATORY TRACT IN CHILDREN PRESENTING WITH RESPIRATORY DISTRESS AT TWO DISTRICT HOSPITALS IN GHANA: EXPLORING HOW CLINICAL PRESENTATIONS RELATE CONFIRMED DIAGNOSES

Frank Baiden[1], Justice Slyverken[2], Kwadwo Nyarko-Jectey[3], Rachel Moresky[4], Harry Tagbor[5], Patrick Wilson[4]

[1]London School of Hygiene & Tropical Medicine, London, United Kingdom, [2]Komfo Anokye Teaching Hospital, Kumasi, Ghana, [3]Mampong Goverment Hospital, Ashanti-Mampong, Ghana, [4]Mailman School of Public Health, Columbia University, New York, NY, United States, [5]School of Medical Sciences, University of Health and Allied Sciences, Ho, Ghana

Overlap in the clinical features of malaria and viral respiratory infections in children present diagnostic and therapeutic challenges in resource-limited settings. We analyzed data on the clinical and laboratory parameters of children presenting with acute respiratory distress at two district hospitals in Ghana. Between Jan 20, 2014, and Dec 5, 2015, we enrolled children one month to five years of age presenting with acute respiratory distress. *Plasmodium falciparum* malaria was tested using rapid diagnostic test (mRDT). Blood smears for microscopy were obtained. Nasopharyngeal

swabs obtained at time of presentation were tested by the BioFire FilmArray PCR assay for 17 viral pathogens. We determine the accuracy of mRDT as compared to blood smears and performed one-way ANOVA to explore differences in clinical parameters. Two thousand children (44.3% female) with a mean age of 17.5months (IQR 9.5-29.0) were enrolled. Mean weight, respiratory rate, pulse, temperature, oxygen saturation and hemoglobin levels were 9.6 (+3.2) kg, 57 (11.2) breaths/min, 152.1 (23.1) beats/min, 37.6C (1.1), 96.9 (+5.0) % and 8.0 gm/dl respectively. Compared with microscopy, mRDT had a sensitivity and specificity of 94% and 60%, respectively. Viral yield was 59%. The main isolated organisms were rhinovirus/enterovirus (36%), respiratory syncytial virus (11%) and parainfluenza (7%). Viral infection among children with or without malaria was 53% and 67% respectively (P<0.01). Significant (P<0.01 in all) differences were observed between children with viral infections only , malaria only , and those with co-infections, respectively as follows; means of weight (8.4kg, 10.5kg, 9.8kg), respiratory rate (59/min, 56/min, 57/min), temperature (37.3C, 37.8C, 37.7C), oxygen saturation (96%, 98%, 97%), hemoglobin levels (8.9gm/dl, 7.2gm/dl, 7.4gm/dl) and total WBC (13.8, 11.5, 13.2). Systematic exploration of the parameters of clinical presentation matched against confirmed diagnosis may improve the accuracy of diagnosis and targeting of medications in resource-limited settings.

1921

HIGH PREVALENCE OF ANXIETY AND DEPRESSION AMONG PATIENTS WITH DENGUE AND NON-DENGUE ACUTE FEBRILE ILLNESS IN SRI LANKA

Champica K. Bodinayake[1], Gayani L. Tillekeratne[2], Wasana S. Ranaweera Arachchige[1], Aruna H. Pushpakumara[1], Piumi K. Wijayaratna[1], Bhagya N. Jayasekera[1]

[1]Faculty of Medicine, University of Ruhuna, Galle, Sri Lanka, [2]Duke University School of Medicine, Durham, NC, United States

Acute fever, notably dengue is a common cause of hospital admission in Sri Lanka and is regarded with fear by the general public. We assessed the prevalence and features associated with anxiety and depression among patients hospitalized with acute fever using the Hospital Anxiety and Depression Scale (HADS) validated for Sri Lanka. We enrolled consecutive patients ≥12 years admitted with acute fever to a tertiary care hospital in Sri Lanka, Jul- Oct 2017. We recorded epidemiological, clinical data and the HADS score. Patients' satisfaction with hospital care and knowledge about illness was recorded using a 5-item Likert scale with 0-3 score on each item. A HADS score of ≥8 was indicative of anxiety or depression. Chi square/ Fisher exact tests and t-test/ Kruskall-Wallis tests were used to identify associations between sociodemographic and clinical variables and anxiety or depression. Of 193 patients, 86 (44.6%) were male; median age was 33 years (IQR 25- 53). A total of 41.4% had anxiety, 42.5% had depression and 26.9% had both. Mean anxiety and depression scores were 7 (IQR 4- 9) and 7 (IQR 4-10), respectively. Patients with anxiety were more likely to have lower income (46.2% vs 30.9, p=0.03), know their diagnosis (95%vs 84.5%, p=0.02), anorexia (81% vs 67%, p=0.03), diarrhea (36% vs 21%, p=0.02), and arthralgia/myalgia (81% vs 68%, p=0.04). Patients with depression were more likely to have headache (83% vs 60.4%, p<0.001), anorexia (85.3% vs 63.9%, p<0.001), vomiting (62.2% vs 41.4%, p<0.01, and diarrhea (39% vs 18.9% p<0.01). Patient knowledge about illness and hospital satisfaction score were not associated with anxiety or depression. Of 121 (62.7% of total) patients with dengue, prevalence of anxiety and depression was similar to no dengue group (43.8% vs 37.5%, p=0.39 and 40.5% vs 45.83%, p=0.46, respectively). Patients hospitalized for acute fever had high levels of anxiety and depression, with similar prevalence among dengue and other fever groups. Anxiety and depression were associated with symptoms and lower economic status. Further measures to improve psychological wellbeing of patients hospitalized with acute fever need to be explored.

1922

DELIVERING CAUSE OF DEATH INFORMATION AT HOUSEHOLD LEVEL IN THE CHILD HEALTH AND MORTALITY PREVENTION SURVEILLANCE (CHAMPS) IN MOZAMBIQUE: IMPLICATIONS FOR MORTALITY SURVEILLANCE DESIGN AND ACTION

Inacio Mandomando[1], Madalena Ripinga[1], Rui Guilaze[1], Carla Carrilho[2], Estevão Mucavele[1], Maria Maixenchs[3], Antonio Sitoe[1], Rosauro Varo[4], Jaume Ordi[4], Elizabeth O´Mara[5], John Blevins[5], Navit Salzberg[5], Pratima Raghunathan[5], Robert Breiman[5], Diana Blau[5], Quique Bassat[4], Clara Menendez[4], Khatia Munguambe[1]

[1]Centro de Investigação em Saúde da Manhiça, Maputo, Mozambique, [2]Faculdade de Medicina, Universidade Eduardo Mondlane, Maputo, Mozambique, [3]ISGlobal, Hospital Clínic - Universitat de Barcelona, Barcelona, Spain, [4]ISGlobal, Hospital Clínic - Universitat de Barcelona, Barcelona, Spain, [5]Emory Global Health Institute, Atlanta, GA, United States

CHAMPS was established in a rural area in Mozambique to ascertain causes of child death (CoD) in order to inform policy and public health action. Minimally Invasive Tissue Sampling (MITS) for histopathology and microbiological CoD assessment are ongoing at the Manhiça District Hospital. Families of deceased under-5 children from the catchment area are approached for consenting to MITS, and CoD results returned to the family. We describe the receptiveness, practicality and usefulness of the CoD results feedback to families for defining public health action. From 12/2016 to 02/2018, 98 of 120 in-hospital MITS-eligible deaths were approached for consent and MITS performed in 80 (82%). CoD were assigned to 46 cases and results returned to 32 families; social behavioral observations of results feedback sessions were conducted on 26 cases. The number of family members present in the sessions varied from 1 to 4, including mothers (in all visits), fathers (in 23% of visits), grandparents (in 54%), and uncles/aunts (46%). Occasionally neighbors and children also participated. The following language was used to explain various causes of death: cerebral malaria (with emphasis on fever effects on the brain); deficient intra-uterine growth; HIV/AIDS; infections in the mother affecting the fetus; loss of breath upon birth; problems in the lungs; limited intake of nutrients; lengthy delivery. The following reactions by family members were captured: the majority felt thankful, linked to sensation of closure, clearance of witchcraft suspicion, the learning experience. However, many blamed themselves (improper child feeding, vertical transmission and delayed treatment-seeking) or the health system (delayed initiative to perform C-section, use of instruments during labor). Results delivery frequently triggered immediate action on the side of families: initiation of antenatal care for new pregnancies, HIV treatment to both parents, accepting treatment of other family members (e.g. syphilis, hypertension), protecting pregnant women from heavy domestic chores. These results have implications for defining strategies to improve health services.

1923

FEBRILE PATIENT MANAGEMENT WORLDWIDE: ANALYSIS OF EXISTING GUIDELINES AND ALGORITHMS TO INFORM NOVEL DIAGNOSTIC AND ALGORITHMIC SOLUTIONS

John Barber[1], Jen Osborn[1], Oscar Bernal[2], Ethan Guillen[2], Cassandra Kelly-Cirino[1], Sabine Dittrich[1]

[1]Foundation for Innovative New Diagnostics, Geneva, Switzerland, [2]Doctors Without Borders (MSF), New York, NY, United States

Fever is one of the most frequently encountered problems worldwide. Clinicians in peripheral clinics and district hospitals (Level 1 & 2 facilities, respectively) in low- and middle-income countries (LMICs) with limited diagnostic capabilities are challenged to manage febrile patients presenting without clear differentiating features. International and national guidelines have been published to improve management of these patients utilizing existing resources. Medecins Sans Frontieres (MSF) and

FIND have partnered to improve febrile patient management by exploring development of a diagnostic system (MAPDx) capable of testing for several pathogens and analytes simultaneously. To inform the use case for this system and to support the development of an MSF febrile illness algorithm, we conducted a landscape analysis of clinical algorithms and guidelines used to manage febrile patients in LMICs with specific attention to the recommended diagnostics. We performed a literature review of PubMed and Cochrane Library and searches of the WHO archives and national Ministry of Health websites. Only documents published in English were included and those intended for Level 1 & 2 facilities were prioritized. We analyzed 4 WHO and 18 national guidelines, 8 algorithms from literature or reference texts, and 7 electronic algorithm applications. WHO guidelines for Level 1 facilities have been widely adopted with minimal changes, while WHO hospital guidelines have not been uniformly adopted and large variation remains across countries. Successful implementation of guidelines contributed to a significant reduction in patient mortality in some settings, while overarching challenges for implementation remain (e.g. poor training, un-sustained investments). Given the envisioned diagnostic system in the ecosystem of existing guideline recommendations, the implementation of such an aspirational diagnostic might best fit within the context of Level 2 facilities. However, substantial additional work is required to enable simple integration and development of improved febrile illness algorithms in multiple settings including at MSF sites.

1924

HEMECHIP: A PORTABLE, AFFORDABLE POINT-OF-CARE DIAGNOSTIC TECHNOLOGY FOR DETECTING HEMOGLOBIN DISORDERS

Umut A. Gurkan[1], Muhammad N. Hasan[1], Arwa Fraiwan[1], Priyaleela Thota[2], Peter Galen[2]

[1]Case Western Reserve University, Cleveland, OH, United States, [2]Hemex Health, Inc., Portland, OR, United States

Genetically inherited hemoglobin (Hb) disorders are of global public health concern. There are more than 700 hemoglobin disorders: HbS, HbC, and HbE are the most widespread Hb variants. HbS and HbC are associated with sickle cell disease. Sickle Cell Disease (SCD) affects between 300,000 to 400,000 newborns every year, and more than 75% of these infants are born in sub-Saharan Africa and India. Of these, WHO estimates that between 50-80% die before reaching age 5. Both the World Health Assembly and the United Nations recognize SCD as a public health priority and have called on countries to tackle the disease. HbE, another structural hemoglobin variant, occurs widely throughout the eastern half of the Indian subcontinent, Bangladesh, Myanmar, and east and southeast Asia. The current clinical standards for diagnostic testing, such as High Performance Liquid Chromatography (HPLC), are associated with high cost per test as well as high cost of infrastructure. Moreover, these clinical standards require centralized laboratories, resulting in delayed turnaround times (several weeks in some regions) and logistical complexities. The geographical regions prevalent with these Hb disorders include some of the lowest-resourced countries in the world, and therefore, early diagnosis of hemoglobin disorders remains a challenge. To address this need, we developed HemeChip, a mass-producible, low-cost version of electrophoresis on a microchip, able to detect and quantify these Hb variants. HemeChip is a robust, highly reliable point-of-care technology that can separate, detect and quantify Hb variants in blood. This rapid (<10 minutes) and easy-to-use test can be performed by minimally trained personnel using only a finger-prick volume of blood. HemeChip can categorize a blood sample as Normal (HbAA), Sickle Cell Trait (HbAS), Sickle Cell Anemia (HbSS), Hemoglobin SC disease (HbSC), and HbE variants. In preliminary tests, with a sample size of 122 (42 HbAA, 36 HbAS, 34 HbSS, and 10 HbSC), HemeChip yielded a high accuracy (> 96%) compared to standard laboratory tests.

1925

QUANTIFYING THE BURDEN OF DIARRHEA AMONG CHILDREN AND ADULTS: INCIDENCE, HOSPITALIZATIONS, AND MORTALITY IN THE GLOBAL BURDEN OF DISEASE STUDY 2017

Ibrahim Khalil, Christopher Troeger, Brigette Blacker, Gregory M. Garcia, Scott Swartz, Simon I. Hay, Robert C. Reiner

Institute for Health Metrics and Evaluation, Seattle, WA, United States

Despite being entirely preventable, diarrhea is the second leading cause of infectious disease globally and the eighth leading cause overall. The Global Burden of Disease study 2017 (GBD 2017) is a systematic, scientific effort to quantify health for all ages, both sexes, every geography, and from 1980-2017. In this presentation we will share methodology and updated results for diarrhea in GBD 2017, focusing on deaths, incidence, and hospitalizations. Deaths, incidence, and hospitalizations were modeled separately using vital registration, verbal autopsy, survey, health records, and scientific literature data and these regression models were strengthened by covariates and by hierarchical space-time trends. Diarrheal diseases were the eighth leading cause of death among all ages in 2017 and the second leading cause of mortality due to infectious diseases (1,540,000 deaths, 95% Uncertainty Interval [UI] 1,140,000-2,250,000). Most of these deaths occurred in children under 5 years (480,000, 95% UI 420,000-530,000) and adults over 70 years (637,000 deaths, 95% UI 370,000-980,000). Diarrhea deaths have decreased by 50% since 1990 among all ages and 75% among children under-5. Despite this dramatic decline globally, deaths have increased by 600% among adults over 70 years old in high-income countries. We estimated 8 billion episodes of diarrhea in 2017 among all ages (95% UI 7.7-9.0 billion) and 13,710,000 hospitalizations due to diarrhea (95% UI 3,470,000 - 52,530,000). The Global Burden of Disease study provides a timely, comprehensive, and detailed picture of the health loss associated with diarrhea and provides public health experts, policy makers, and health officials with evidence for decision making and a roadmap for reducing the burden of diarrhea.

1926

PRELIMINARY PERFORMANCE OF THE BIOFIRE® FILMARRAY® TRAVEL-RELATED FEBRILE ILLNESS PANEL AT THE MAHOSOT HOSPITAL IN VIENTIANE, LAOS

Matthew T. Robinson[1], **Mike Vaughn**[2], Nerissa Spampanato[2], Brandon Hanberg[2], Crystal Smith[2], Robert Trauscht[2], Ashley Hillman[2], Pruksa Nawtaisong[1], Soulignasak Thongpaseuth[1], Malavanh Vongsouvath[1], Ooyanong Phonemixay[1], Neeranuch Thangnimitchok[1], Bart Kensinger[2], Paul Newton[1], Robert Crisp[2]

Fever is a common symptom in returned travelers and an important marker of potentially serious illness. While many of the symptoms of febrile patients are non-specific and over-lapping, it is important to distinguish between viral syndromes, bacterial or parasitic infections, or non-infectious causes of fever to timely determine correct treatment. BioFire Diagnostics, LLC has developed a polymerase chain reaction (PCR), high-resolution melting analysis instrument called the FilmArray. The BioFire Travel-Related Febrile Illness (TRFI) Panel is a reagent pouch in development for use with the FilmArray instrument that contains freeze-dried reagents to perform nucleic acid purification and multiplex PCR for the identification of nine viral, seven bacterial, and eight parasitic pathogens that cause systemic infections in febrile patients from a single specimen. Three hundred and twenty whole blood samples, prospectively collected from patients admitted to Mahosot Hospital with acute, undifferentiated fever were tested using the BioFire TRFI Panel. When possible, BioFire TRFI Panel testing results were compared to those from the hospital Microbiology Laboratory molecular diagnostic testing.

BioFire TRFI Panel testing resulted in 110 (34%) positive detections and included Dengue virus (97), *Leptospira* spp. (2), *Orientia tsutsugamushi* (6), *Plasmodium vivax* (1), *Rickettsia* spp. (2), and *Salmonella* spp. (2). For samples in which BioFire TRFI Panel and hospital laboratory results could be compared, positive agreement for the detection of Dengue virus was 98.7% (78/79) with a negative agreement of 69.0% (20/29). Negative agreement comparisons were available for *Leptospira* spp. (21/21), *O. tsutsugamushi* (4/6), *Rickettsia* spp. (20/20), *Salmonella* spp. (7/7), Chikungunya virus (107/107), and Zika virus (86/86). These results indicate that the BioFire TRFI Panel could provide a fast, multi-pathogen testing platform for aiding in the etiological diagnosis of acute travel-related febrile illness. This abstract contains information regarding assays that have not been reviewed by regulatory agencies for *in vitro* diagnostic use.

1927

SUSCEPTIBILITY OF *CANDIDA* ISOLATES FROM FEMALES PRESENTING WITH CANDIDAL VAGINITIS AT THREE GHANAIAN HOSPITALS TO FORMULATIONS OF *CRYPTOLEPIS SANGUINOLENTA* ROOT

Sylvester Kaminta[1], Mark A. Appenteng[1], Gloria Adjapong[1], Jerry Aseidu-Larbi[1], Augustine A. Ocloo[2], Olga Quarsie[2], Doris Kumadoh[2], Abdul-Salim Musah[3], Maxwell Antwi[4], Francis Ahireng[4], Felix C. Mills-Robertson[5]

[1]Department of Microbiology, Centre for Plant Medicine Research (CPMR), Mampong-Akuapem, Ghana, [2]Department of Pharmacology, Centre for Plant Medicine Research (CPMR), Mampong-Akuapem, Ghana, [3]Department of Emergency Medicine, St. Theresa Hospital, Nandom, Upper-West, Ghana, Nandom, Ghana, [4]Tetteh Quashie Memorial Hospital, Mampong-Akwapim, Ghana, Mampong-Akuapem, Ghana, [5]Department of Biochemistry and Biotechnology, Kwame Nkrumah University of Science and Technology, Kumasi, Ghana

Following claims that *Cryptolepis sanguinolenta* (Linn.) Schltr has antimicrobial activity against some infectious microbes, an *in vitro* anticandidal activities of two formulations of *C. sanguinolenta*, *C-Root-A* and *C-Root-B* were evaluated against nine clinical isolates of *Candida* species and a standard strain of *Candida albicans,* using the agar well diffusion method. The results obtained from the present investigation revealed that both *C-Root-A* and *C-Root-B* formulations exhibited antifungal activity against all test *Candida* species with the highest activity exhibited by the *C-Root-A* against *Candida spp (*K'bu-1) at the concentration of 200 mg/ml (zone of inhibition 28.9 ± 0.3 mm). Antifungal activities were recorded for all the test concentrations of *C-Root-A* with the diameters of zones of inhibitions decreasing with decreasing concentrations of the product (200 mg/ml to 12.5 mg/ml). Period of incubation (24 – 72 h) had no significant effect on the diameter of zones of inhibition ($p \leq 0.05$), suggesting the products may have fungicidal effect against the test organisms. The study confirmed that of *C. sanguinolenta* has anticandidal activity and could be used to formulate products for the treatment of candidal infections.

1928

IMPACT OF MALARIA, PNEUMONIA AND DIARRHEAL ILLNESS ON CHILD GROWTH IN PAPUA NEW GUINEA

Maria A. Ome-Kaius[1], Sophie G. Zaloumis[2], Patricia Rarau[2], Thomas Obadia[3], Mary Salib[4], Doris Manong[4], Stephen Rogerson[2], Ivo Mueller[1], Leanne J. Robinson[1]

[1]Walter and Eliza Hall Institute of Medical Research, Melbourne, Australia, [2]University of Melbourne, Melbourne, Australia, [3]Institut Pasteur, Paris, France, [4]PNG Institute of Medical Research, Madang, Papua New Guinea

The first 1000 days of a child's life is a critical period for child development, where inadequate nutrition and infectious disease can not only increase risk of serious illness and death but have long term adverse health, developmental and socioeconomic outcomes. In many low to middle income countries including Papua New Guinea (PNG), infectious diseases and undernutrition are highly prevalent and are major contributors to high rates of early childhood illness and death. Undernutrition and infectious diseases are believed to have a bi-directional causal relationship but the impact of infectious diseases on growth is complex and poorly understood. Using passive case surveillance data from a large malaria prevention trial in PNG, we investigated the impact of the three commonly occurring infectious diseases in PNG (malaria, pneumonia and diarrheal diseases) on child growth. Children were enrolled at 3 months of age and actively monitored every 3 months for a total of 2 years (720 days) with weights measured at every three-monthly visit and heights were only taken at 15 and 27 months of age. Analysis included 1605 children with a total of 8950 illness episodes with 1885 malaria, 2611 pneumonia and 1655 diarrheal disease episodes recorded over the study period. A total of 11352 weights and 2060 height measurements were taken with corresponding WHO standardized z-scores. A total of 28 lags of 30 days each were defined. Preliminary analysis fitting a basic hierarchical distributed lag model with linear basis for the lags suggested an impact of malaria on weight the longer the lag was. However, this model will be extended to allow for non-linear associations between lag times for the different number of episodes of malaria and weight. Analysis for the effect of pneumonia and diarrheal illness will also performed and the final results will be presented at the meeting.

RETURNING TRAVELER WITH AN ULCERATING BUG BITE: LEISHMANIASIS MISDIAGNOSED AS SQUAMOUS CELL CARCINOMA

Sigrid M. Collier, Cuong V. Nguyen, Daniel D. Miller

University of Minnesota, Minneapolis, MN, United States

We present a case of cutaneous leishmaniasis that was misdiagnosed as a squamous cell carcinoma. We also review the literature on the adverse outcomes associated with this misdiagnosis and discuss the clinical challenge of skin disease in the returning traveler. A 48-year-old female who had recently traveled to Panama presented to a clinic with an ulcerated nodule on the left dorsal forearm. Her initial work-up and treatment included negative bacterial cultures and a course of oral valacyclovir without clinical response. She eventually underwent a skin biopsy and was diagnosed with a poorly differentiated squamous cell carcinoma. She was treated with mohs micrographic surgery, but the surgeon felt the tumor was still present at the margin despite extensive surgery. She was then referred to the University of Minnesota for additional mohs micrographic surgery. At the time of her evaluation the patient had developed several new subcutaneous nodules in the left antecubital fossa, and the case was re-evaluated by dermatopathology. Review of the biopsies demonstrated pseudoepitheliomatous hyperplasia, which on histopathology can mimic squamous cell carcinoma. However, within the inflammation under the reactive skin there were multiple scattered intracellular amastigotes. The patient's ultimate diagnosis, which was confirmed by the Center for Disease Control, was *leishmaniasis panamensis*. After 4 weeks of oral miltefosine her symptoms completely resolved. There are at least five case reports of leishmaniasis misdiagnosed as squamous cell carcinoma. Many of the patients underwent large unnecessary surgical procedures prior to receiving the correct diagnosis. Skin disease is common in the returning traveler with 19.5% of travelers reporting skin disease in the GeoSentinel Surveillance data. Despite the prevalence of dermatologic diseases in returning travelers these medical errors still occur. This is likely due to limited familiarity with cutaneous tropical diseases, non-specific clinical presentations, the paucity of available disease specific diagnostic tests, and the lack of clinicians trained in tropical skin disease.

THE ETIOLOGIES AND OUTCOMES OF SEPSIS IN PATIENTS WITH ACUTE FEBRILE ILLNESS IN INDONESIA: RECOMMENDATIONS FOR FUTURE DIRECTIONS

Rizka Humardewayanti Asdie[1], Khie Chen Lie[2], Sudirman Katu[3], Mochamad Helmi Aziz[4], Usman Hadi[5], I. Made Utama[6], Nurhayati Nurhayati[4], Muhammad Karyana[7], Herman Kosasih[4], Emiliana Tjitra[4], Bachti Alisjahbana[8], M. Hussein Gasem[9], for INA-RESPOND Network[4]

[1]Gadjah Mada University/Dr. Sardjito Hospital, Yogyakarta, Indonesia, [2]University of Indonesia/Dr. Cipto Mangunkusumo Hospital, Jakarta, Indonesia, [3]Hasanuddin University/Dr. Wahidin Sudirohusodo Hospital, Makassar, Indonesia, [4]Indonesia Research Partnership on Infectious Disease (INA-RESPOND), Jakarta, Indonesia, [5]Airlangga University/Dr. Soetomo Hospital, Surabaya, Indonesia, [6]Udayana University/Sanglah Hospital, Denpasar, Indonesia, [7]National Institute of Health Research and Development (NIHRD), Ministry of Health Republic of Indonesia, Jakarta, Indonesia, [8]Padjajaran University/Dr. Hasan Sadikin Hospital, Bandung, Indonesia, [9]Diponegoro University/Dr. Kariadi Hospital, Semarang, Indonesia

Case fatality rate of acute febrile illness (AFI) is often high when sepsis occurs. In low resource settings it is often difficult to establish a diagnosis of sepsis from the clinical presentations and physical examination, since sepsis share similar clinical features with other disorders. Ideally, a guideline for sepsis treatment should be adjusted based on epidemiology data built from national surveillance studies. To identify the etiology of AFI and the clinical outcomes, an observational study, Acute Febrile Illness Requiring Hospitalization (AFIRE), was conducted at 8 top-referral hospitals across Indonesia from 2013 to 2016. Hospitalized subjects were enrolled and visited 24 hours, 14-28 days, and 3 months after enrollment. Blood, other biological specimens (if available) and clinical data were collected during these visits. Later the specimens were screened for more than 50 different pathogens using molecular and serological methods. 59 from 1486 subjects were enrolled with clinical diagnosis of sepsis (38 subjects) or had sepsis (21 subjects) during hospitalization. The mean period of fever onset in subjects with sepsis was 5.3 days (SD 3.2 days) and the mean period of hospitalization was 7.8 days (SD 7.9 days). Twenty-one subjects (35.5%) discharged from the hospital and thirty-eight (64.4%) died during the hospitalization, among which 27 (71.0%) had underlying diseases such as HIV, TB, malnutrition, anemia, congenital malformation, cardiovascular and metabolic disease. Thirty-five (59.3%) had confirmed etiologies of sepsis, 27 were bacterial pathogens (8 *R. typhi,* 3 *Salmonella spp.,* 3 *S. aureus*, 2 *Leptospira spp.,* 2 *Escherichia coli,* 2 *M. tuberculosis,* 2 *S. pneumoniae,* 1 *E. aerogenes,* 1 *E. faecalis,* 1 *M. leprae,* 1 *P. aeruginosa, and* 1 *S. faecalis*), and 7 were viruses (3 influenza, 2 dengue, 1 HHV-6, and 1 acute HIV infection), and 1 parasite (*A. lumbricoides*). The findings of this study will aid the national health policy program to develop guidelines for diagnosis and treatment of sepsis caused by AFI and highlight the importance of enhancing diagnostic capacity on infectious diseases in Indonesia.

1931

EFFECT OF COMORBIDITIES ON LINEAR GROWTH: A COHORT STUDY OF CHILDREN AT RISK FOR ENVIRONMENTAL ENTERIC DYSFUNCTION

Zehra Jamil[1], Najeeha Iqbal[1], Sana Syed[2], Kamran Sadiq[1], T. Akhund[1], Fayaz Umrani[1], Najeeb Rahman[1], Shahida Qureshi[1], Syed Ali[1]

[1]Aga Khan University, Karachi, Pakistan, [2]Aga Khan University, University of Virginia School of Medicine, WV, United States

Pakistan has high prevalence of stunting (44%) in children <5y of age. Stunting (height for age Z score (HAZ)<-2)/ linear growth faltering is associated with irreversible physical and neurocognitive damage these children. Lower birth weight is known to be a major determinant of poor linear growth and increased frequency of infectious comorbidities in subsequent years. Insulin like growth factor (IGF) is protein that plays critical role in the growth hormone/IGF-1 axis. We aimed to study the relationship of birth weight with serum Insulin like growth factor (IGF), comorbidities and linear growth (as measured by HAZ). 380 newborns were prospectively enrolled in a community-based cohort and followed longitudinally with monthly anthropometric measurements and weekly surveillance for diarrheal days, fever and cough or runny nose. IGF was assessed from serum samples at 6 and 9m. Data was analyzed by SPSS 21. We correlated birth weight with HAZ at 18m and frequency of diarrhea, cough & runny nose and fever. Lower birth weight significantly correlated with higher frequency of fever at 6m and 9m(r=-0.135;p=0.009,r=-0.124;p=0.027), diarrhea at 9m (r=-0.154;p=0.006) and HAZ at 18m(r=0.328;p<0.001). Increasing frequency of fever showed a negative correlation with IGF at 6m only (r=-0.111;p=0.051). However, significant positive correlation was observed for IGF at 6 and 9m with HAZ at 18m (r=0.237;p<0.001, r=0.314;p<0.001). An interesting finding of note was the correlation among comorbidities at both 6m [diarrhea with fever (r=0.262;p<0.001), diarrhea with cough & runny nose (0.251;p<0.001) and fever with cough & runny nose (r=0.478;p<0.001)] and at 9m [diarrhea with fever (r=0.323;p<0.001), diarrhea with cough & runny nose (0.347;p<0.001) and fever with cough & runny nose (r=0.542;p<0.001)]. Yet, non-significant association was observed between comorbidities and HAZ at 18m. Linear growth faltering/ stunting is a multifactorial process driven by birth weight which may be influenced by repeated infections with or without the involvement of IGF.

1932

PERSISTENTLY LOW VIRAL LOAD FOR HBV IN PATIENTS WITH HEPATOCARCINOMA IN PERU 2013 - 2015

Cesar Cabezaq[1], Johanna Balbuena[2], Eloy Ruiz[3]

[1]Instituto Nacional de Salud, Lima, Peru, [2]Instituto National de Salud, Lima, Peru, [3]Instituto Nacional de Enfermedades Neoplasicas, Lima, Peru

Before the implementation of the immunization program against Hepatitis B, the Amazon region and some inter-Andean valleys in Peru used to be considered as HBV hyperendemic areas. Nonetheless, some people infected before the application of the HBV vaccine remain as chronic carriers. The internationally standardized recommendation is to start treatment if the viral load of HBV is greater than 2,000 IU / ml. In order to determine viral load levels in patients with a diagnosis of hepatocarcinoma, 35 patients with histopathological diagnosis were evaluated, from the National Institute of Neoplastic Diseases (Lima-Peru). Blood samples were obtained to determine the serological markers for HBV using the ELISA technique and the HBV viral load (qRT-PCR). Demographic data such as sex, age, origin and history of illness were collected in a clinical record. The average age was 30.4 years, (CI 18 -72 years). 65.7% were male and 20% (7/35) were from hyperendemic areas of hepatitis B (Cusco, Ayacucho and Apurímac). 96.55% of the 35 participants were HBsAg (+), 100% anti HBc total (+), 100% HBc-IgM (-) and 100% HBeAg (-). The viral load was undetectable in 7/35 people, <20 IU / mL in 13/35; between 50- 1163 IU / mL in 12/35 and only in 1/35 (3%) had a viral load for HBV> 2,000 IU / mL. In conclusion, based on the international parameters (> 2,000UI / mL), only 1 of 35 (3%) patients with hepatocarcinoma would require treatment according to established norms, which suggests that the viral load parameter should be re-evaluated as a criterion of treatment for patients with chronic hepatitis B in the studied population.

1933

UTILITY OF Q PCR ASSAY AS A CLINICALLY RELEVANT DIAGNOSTIC TEST

R.M I. Senavirathna[1], Y. P. Warnasekara[2], J. M. Jayasundara[3], D. A. Hettiarachchi[2], M. Matthias[4], J. M. Vinetz[4], S. B. Agampodi[2]

[1]Department of Biochemistry, Faculty of Medicine and Allied Sciences, Rajarata University of Sri Lanka, Anuradhapura, Sri Lanka, [2]Department

of Community Medicine, Faculty of Medicine and Allied Sciences, Rajarata University of Sri Lanka, Anuradhapura, Sri Lanka, [3]Department of Microbiology, Faculty of Medicine and Allied Sciences, Rajarata University of Sri Lanka, Anuradhapura, Sri Lanka, [4]Division of Infectious Diseases, Department of Medicine, University of California, San Diego, San Diego, CA, United States

Quantitative Polymerase Chain Reaction (qPCR) has been tested in archived samples successfully as an early diagnostic test for leptospirosis. We carried out a prospective hospital-based study in Teaching hospital Anuradhapura, the third largest hospital in Sri Lanka to provide routine qPCR diagnosis for leptospirosis as a clinically relevant diagnostic test. Febrile patients were consecutively recruited on the first encounter and a previously validated qPCR assay targeting 16s ribosomal gene of pathogenic *Leptospira spp* was done using CFX96 real-time PCR detection system (Bio-Rad). Those samples with a Ct value<40 and a melt curve in duplicate wells were considered as confirmed cases. First 207 samples included all fever patients without a diagnosis and both serum and whole blood (WB) were tested for comparison. The rest were possible leptospirosis patients. Altogether, 362 undifferentiated febrile patients; 30(8.3%) from OPD and 332(91.7%) from wards were recruited. Of them, 1 (3.3%) and 79 (23.8%) were confirmed with qPCR from OPD and wards respectively. The Ct values ranges from 24 to 40 in positive cases, with a mean of 35. Among 75.7% of the positive patients, sample collection was done within the first five days of illness. For all urgent samples, results were issued within 24 hours of request. In the first 207 samples, only 7(3.4%) were positive in WB. Only four of those were positive for serum. The Ct value for the serum and whole blood ranged from 29-37 and 25-39 respectively. Whole blood samples consistently produced early signals with an average Ct difference of 4 compared to serum. The three samples, which were only positive with WB, had Ct values between 38 and 39. An independent spiking experiment with serum and WB confirmed higher sensitivity of WB in which the standard curves showed an average Ct different of 2 in lower concentrations. We demonstrated that qPCR could be used as a clinically relevant diagnostic tool in early diagnosis of leptospirosis, even in remote settings with minimal facilities.

1934

SCALING-UP ACCESS TO OXYGEN IN 3 STATES IN NIGERIA: A PROGRAM EVALUATION

Felix Lam[1], Chizoba Fashanu[2], Tinsae Mekonnen[3], Katherine Schroder[1], Owens Wiwa[2]

[1]Clinton Health Access Initiative, Boston, MA, United States, [2]Clinton Health Access Initiative, Abuja, Nigeria, [3]Clinton Health Access Initiative, Addis Ababa, Ethiopia

Hypoxemia, or lack of oxygen in the blood, is a fatal condition commonly found in pediatric patients with pneumonia. The WHO recommends pulse oximetry for detecting hypoxemia and oxygen for treatment. In Nigeria, access to these medical interventions is limited. The Clinton Health Access Initiative (CHAI) supported the state governments of Kano, Kaduna, and Niger to install oxygen systems in pediatric wards of 30 facilities and trained healthcare providers to use the system and biomedical engineers on maintenance. We evaluated whether the program increased the use of pulse oximetry among pediatric patients presenting to the study facilities with respiratory illness and the use of oxygen therapy for treatment of hypoxemia. The study design was a pre- vs. post-intervention comparison. We conducted monthly reviews of medical records for all pediatric patients under age 5 and with a respiratory illness diagnosis. Data was collected from Jan 2017 through Aug 2018 with the pre-intervention period defined as Jan-Aug 2017 and the post-intervention period as Jan-Aug 2018. We excluded Sep-Dec 2017 since the interventions occurred during this period. The primary outcomes of interest of the study were (1) whether patients diagnosed with a respiratory illness had a documented arterial blood oxygen saturation measurement, SpO2, in their medical records, and (2) whether patients with clinical signs of hypoxemia were prescribed oxygen therapy. We reviewed 3,354 medical records at baseline. Baseline results show that prior to the intervention, 6.2% (95% CI 2.4%, 14.6%) of all under-5 respiratory illness cases had a SpO2 measurement. Among the records reviewed, 580 (17.29%) had documented signs of clinical hypoxemia, and at baseline, 16.5% (95% CI 7.3%, 33%) of hypoxemic patients were prescribed oxygen therapy. Data collection is ongoing for the post-intervention period and will be available by October 2018.

1935

FLUBENDAZOLE: ROBUST PRECLINICAL DATA SUPPORT DECISION TO DISCONTINUE DEVELOPMENT IN FILARIAL WORM INFECTIONS

Benny Baeten[1], Marc Engelen[1], Sophie Lachau-Durand[1], Lieve Lammens[1], Petros Psathas[2], Ludo Quirynen[1], Lieven Stuyver[1], Fetene Tekle[1], Melissa Tokosh[2]

[1]Janssen R&D & Global Public Health, Beerse, Belgium, [2]Janssen R&D & Global Public Health, Raritan, NJ, United States

Onchocerciasis, caused by the filarial parasitic worm, *Onchocerca volvulus*, is a major cause of infection-related skin disease and blindness in Africa. It is a Neglected Tropical Disease targeted for elimination. Since regimens used in Mass Drug Administration kill the larvae, but not the adult worms, a macrofilaricidal drug would accelerate progress towards elimination. Flubendazole (FBZ) is a benzimidazole anthelmintic used to treat intestinal worm infections. Subcutaneous (sc) administration is very effective in killing adult filarial worms and is generally used as a positive control in animal efficacy studies. To explore its efficacy after oral administration, Johnson & Johnson developed an Amorphous Solid Dispersion, and studied its preclinical toxicology, pharmacokinetics (PK) and efficacy. The efficacy and PK of single-dose sc administrations were also tested. Efficacy studies were performed in well-established models at Bonn University (A Hoerauf, M Hübner), UCLA (J Sakanari) and LSTM (J Turner). Oral administration of FBZ required high doses and/or long treatments to reach sufficient macrofilaricidal effect. Single sc injections led to sustained systemic exposure and were highly effective. Toxicology studies showed that, in line with its mechanism of action as a tubuline inhibitor, FBZ targets cell division and foetal development, with potential for carcinogenicity, embryotoxicity and testicular effects. Long exposures to systemically available FBZ are therefore not recommended. The company concluded that no efficacious dose could be selected that would be safe to enter the clinic, and decided to discontinue development of FBZ in filarial diseases. The authors will present the development path of FBZ and will explain that, even if the outcome was discontinuation, the project is considered successful, since the decision was based on robust data and new insights, that can help advance the field. In parallel with preclinical development, a search for clinically relevant *Onchocerca*-specific biomarkers was undertaken. The results of those efforts will be presented separately.

1936

ATYPICAL PATTERNS OF *LOA LOA* MICROFILARIA DENSITIES IN GABON

Luzia Veletzky[1], Jennifer Hergeth[2], Daniel Stelzl[2], Matthew McCall[2], Rella Zoleko-Manego[2], Johannes Mischlinger[1], Ghyslain Mombo-Ngoma[2], Wolfram Metzger[3], Ayôla A. Adegnika[2], Peter G. Kremsner[3], Benjamin Mordmüller[3], Michael Ramharter[1]

[1]Bernhard-Nocht-Institute for Tropical Medicine and University Medical Center Hamburg-Eppendorf, Hamburg, Germany, [2]Centre de Recherches Médicales de Lambaréné, Lambaréné, Gabon, [3]Institut für Tropenmedizin, Universität Tübingen, Tübingen, Germany

Loa loa are microfilariae producing roundworms highly endemic in west and central Africa. These microfilariae can be diagnosed in peripheral blood by direct examination or after concentration techniques. Classically, a diurnal periodicity with microfilariae density peak around noon was described and thought to be an adaptation to the diurnal behavior of the main vector. Based on this observation blood withdrawals for *L. loa* microfilariae diagnostics are recommended to be performed between

10am and 3pm. However, these fluctuations of microfilariae counts have only scarcely been studied. Recent case series have challenged this feature of loiasis. The objective of this study was therefore to reevaluate the dogma of diurnal periodicity of *L. loa* microfilaremia. The study was performed at the Centre de Recherches Médicales de Lambaréné, situated in central Gabon. Patients diagnosed to harbor *L. loa* microfilariae within another study were explained the rationale of the project and invited to participate. If participants accepted, four consecutive finger pricks were performed within a 24hours time period. Finger pricks were performed at 6am, noon, 6pm and midnight. From each finger prick, two thick blood smears using each 10ul blood were prepared. Finger pricks were dried and stained using Giemsa stain. Thick blood smears were then read by two trained microscopists, which were blinded to each other's results. Absolute microfilariae counts of both thick blood smears were added and extrapolated to a Mf/mL count. Readings of 22 participants showed a diverse picture of midday microfilariae densities with counts between 50 and 100,900 Mf/mL. No clear circadian periodicity of microfilaremia was observed during the different observation points (p=0.54; ANOVA). Interestingly, only one patient became negative for *L. loa* microfilariae during night time, while in the others microfilariae remained detectable. These results show an atypical pattern of microfilariae densities within the studied population and question the classical dogma of clear diurnal periodicity of *L. loa* microfilaremia.

1937

A BURDEN OF DISEASE ASSESSMENT OF *LOA LOA* INFECTION IN GABON

Luzia Veletzky[1], Jennifer Hergeth[2], Daniel Stelzl[2], Rella Zoleko-Manego[2], Lia B. Mbaginga[2], Ghyslain Mombo-Ngoma[2], Christine Budke[3], Johannes Mischlinger[1], Ayôla A. Adegnika[2], Wolfram Metzger[4], Pierre B. Matsiegui[5], Heimo Lagler[6], Peter G. Kremsner[4], Benjamin Mordmüller[4], Michael Ramharter[1]

[1]Bernhard-Nocht-Institute for Tropical Medicine and University Medical Center Hamburg-Eppendorf, Hamburg, Germany, [2]Centre de Recherches Médicales de Lambaréné, Lambaréné, Gabon, [3]Texas A&M University, College Station, TX, United States, [4]Institut für Tropenmedizin, Universität Tübingen, Tübingen, Germany, [5]Centre de Recherches Medicales de la Ngounié, Fougamou, Gabon, [6]Medical University of Vienna, Vienna, Austria

Loiasis is a parasitic infection highly endemic in west and central Africa. Previously often considered as a benign infection studies have recently suggested that high microfilaria loads in *L. loa* patients may be associated with raised mortality. The true impact of loiasis on affected communities is unknown. Burden of disease studies including calculation of disability adjusted life years are a well proven tool to assess objectively the impact of a disease on an affected population. However, in-depth studies about clinics and on disease impact in endemic populations have never been performed for *L. loa*. Therefore, further studies are needed to increase current knowledge and to evaluate the impact of this parasitosis. This cross-sectional study was performed in rural Gabon to establish the burden of disease of loiasis. Inclusion criteria were local residency for at least two years and an age above two years. Participants were interrogated a standardized questionnaire covering loiasis specific symptoms, history of eye worm and health care seeking behavior. History of eye worm was assessed using the standardized RAPLOA questionnaire and local vocabulary was employed if needed. In case of children, parents were interviewed or assisted during the questioning. At the same time *L. loa* microfilaria diagnostics were performed including thick blood smear preparation and concentration techniques. Peripheral blood withdrawals were done between 10am and 3pm. 980 participants were recruited, of which 56% were female and aged between 2 to 98 years. *L. loa* microfilariae were detectable in 27% of all participants. Microfilariae densities ranged from 1 to 76250 Mf/mL. Overall a positive history of eye worm was reported in 56%, with 25% of participants reporting eye worm passage within the last year. Of those, 93% stated that eye worm passage was accompanied by severe local pain and 76% reported concomitant visual disturbances. Furthermore, 60% had stayed at home during worm passage, not being able to follow their daily work. Based on these data a burden of disease analysis was performed establishing the disability adjusted life years for affected communities.

The true impact of loiasis on affected communities is unknown. Burden of disease studies including calculation of disability adjusted life years are a well proven tool to assess objectively the impact of a disease on an affected population. However, in-depth studies about clinics and on disease impact in endemic populations have never been performed for *L. loa*. Therefore, further studies are needed to increase current knowledge and to evaluate the impact of this parasitosis. This cross-sectional study was performed in rural Gabon to establish the burden of disease of loiasis. Inclusion criteria were local residency for at least two years and an age above two years. Participants were interrogated a standardized questionnaire covering loiasis specific symptoms, history of eye worm and health care seeking behavior. History of eye worm was assessed using the standardized RAPLOA questionnaire and local vocabulary was employed if needed. In case of children, parents were interviewed or assisted during the questioning. At the same time *L. loa* microfilaria diagnostics were performed including thick blood smear preparation and concentration techniques. Peripheral blood withdrawals were done between 10am and 3pm. 980 participants were recruited, of which 56% were female and aged between 2 to 98 years. *L. loa* microfilariae were detectable in 27% of all participants. Microfilariae densities ranged from 1 to 76250 Mf/mL. Overall a positive history of eye worm was reported in 56%, with 25% of participants reporting eye worm passage within the last year. Of those, 93% stated that eye worm passage was accompanied by severe local pain and 76% reported concomitant visual disturbances. Furthermore, 60% had stayed at home during worm passage, not being able to follow their daily work. Based on these data a burden of disease analysis was performed establishing the disability adjusted life years for affected communities.

1938

MASS DRUG ADMINISTRATION FOR LYMPHATIC FILARIASIS IN AN URBAN AREA OF CROSS RIVER STATE NIGERIA

Thomas Igbang[1], Benjamin Nwobi[2], Samson Olorusongo[2], Wangeci Thuo[3], Michael French[3]

[1]Cross River State Ministry Of Health, Calabar, Nigeria, [2]RTI International, Abuja, Nigeria, [3]RTI International, Washington, DC, United States

The challenges of conducting mass drug administration in urban settings is well documented. These challenges include, but are not limited to, lack of trust, inadequate numbers of health workers, migrant populations, and disorganized poor urban settlements. Calabar South local government area (LGA) in Cross River State, Nigeria, faces these challenges. The LGA

has a population of 235, 388. Mapping of neglected tropical diseases (NTDs) showed that the entire population is at risk for lymphatic filariasis (LF). The LGA is also endemic for soil transmitted helminths, however prevalence is low and treatment is not required. The LGA has conducted at least seven annual rounds of mass drug administration (MDA) for LF with Albendazole and Ivermectin since 2011, and has only successfully reached the target 65% of people at risk, three times. Reports from the community drug distributers (CDDs) and supervisors from the LGA revealed that many people in Calabar South go to work in neighbouring LGAs and therefore the CDDs would find nobody at home when they conducted MDA. Through discussions with the community and LGA leaders, they mapped internal migration patterns - residents of Calabar South go to work in Calabar North during the day and many residents frequented the market and places of worship during the weekends. With this information, the LF program set out to mobilize not only community drug distributers but also faith-based organization' members, Rotary club members, and university students to distribute treatments in homes, places of worship and markets. LF increased from 43% in 2016 to 97% in 2017. Because if these efforts, Calabar South has now achieved four effective rounds of LF MDA and is on the path to stop treatment in 2018 and become eligible to conduct pre-Transmission assessments survey in 2019.

1939

A RANDOMIZED CLINICAL TRIAL TO STUDY THE IMPACT OF TREATMENT WITH SEMIANNUAL ALBENDAZOLE FOR LYMPHATIC FILARIASIS IN COTE D'IVOIRE

Aboulaye Meite[1], Catherine M. Bjerum[2], Allassane Ouattara[3], Benjamin Koudou[4], Koffi Marius Vanga[3], Olivier Kouadio[3], Gary Weil[5], Christopher King[2]

[1]Programme national de la lutte contre l'onchocercose, la schistosomiase, les geohelminthiases et la filariose lymphatique, Abidjan, Côte D'Ivoire, [2]Case Western Reserve University, Cleveland, OH, United States, [3]Centre Suisse de Recherche Scientifique en Côte d'Ivoire, Abidjan, Côte D'Ivoire, [4]Liverpool School of Tropical Medicine, Abidjan, United Kingdom, [5]Infectious Diseases Division, Department of Internal Medicine, Washington University School of Medicine, St. Louis, MO, United States

Implementation of mass drug administration (MDA) with ivermectin (IVM) plus albendazole (ALB) for lymphatic filariasis (LF) has been deferred in many parts of Africa where *Loa loa* is co-endemic because ivermectin can induce serious adverse events in people with high level *Loa loa* microfilaremia. WHO now recommends ALB MDA alone with vector control to reduce LF in areas with co-endemic loiasis. This study tested the efficacy of semiannual treatment with ALB 400mg or ALB 800mg. We conducted an open-label randomized clinical trial in which *Wuchereria bancrofti*-microfilaremic adults in Cote d'Ivoire were assigned to treatment with IVM/ALB annually x 3 (n=48), ALB 400mg semiannually x 6 (n=45), and ALB 800mg semiannually x 6 (n=47). Clearance of blood microfilaria and adult worm nests was measured at 6, 12, 24 and 36 months. 36 months results will be collected in July 2018. IVM/ALB cleared Mf in 15 of 45 (33%), 10 of 43 (23%) and 22 of 40 (55%) at 6, 12 and 24 months respectively. At the same time points ALB 400mg cleared Mf in 2 of 40 (5%), 7 of 36 (19%) and 12 of 34 (35%, risk relative to IVM/ALB at 24 months =1.4, P=0.09). ALB 800mg cleared Mf in 1 of 40 (3%), 7 of 42 (17%) and 11 of 37 (30%, risk relative to IVM/ALB at 24 months=1.6, P=0.03) at 6, 12, and 24 months respectively. At 24 months IVM/ALB, ALB 400mg and ALB 800mg produced 93%, 77% and 71% reduction in Mf levels compared to baseline. Among participants that had worms nests at baseline, 50%, 19% and 25% of individuals had complete inactivation of detectable worm nests at 24 months for IVM/ALB, ALB 400mg and ALB 800mg arms respectively. The overall reduction Mf levels at 12 and 24 months in positively correlated with number of worm nests inactivated (r^2 = 0.52, P=0.007). Semiannual treatment with ALB alone produced a significant reduction in Mf levels, but was inferior to annual IVM/ALB at 24 months. ALB 800mg provided no benefit compared to ALB 400mg.

1940

IDENTIFYING RESIDUAL TRANSMISSION OF LYMPHATIC FILARIASIS AFTER MASS DRUG ADMINISTRATION - COMPARING SCHOOL-BASED VERSUS COMMUNITY-BASED SURVEILLANCE, AMERICAN SAMOA, 2016

Meru Sheel[1], Sarah Sheridan[1], Katherine Gass[2], Kimberly Y. Won[3], Saipale Fuimaono[4], Martyn Kirk[1], Amor Gonzales[5], Shannon Hedtke[6], Patricia M. Graves[7], Colleen L. Lau[1]

[1]Research School of Population Health, The Australian National University, Canberra, Australia, [2]Neglected Tropical Disease Support Center, The Task Force for Global Health, Decatur, GA, United States, [3]Centers for Disease Control and Prevention, Division of Parasitic Diseases and Malaria, Atlanta, GA, United States, [4]American Samoa Department of Health, Pago Pago, American Samoa, [5]LBJ Tropical Medical Center, Pago Pago, American Samoa, [6]Department of Animal, Plant and Soil Sciences, La Trobe University, Bundoora, Australia, [7]College of Public Health, Medical and Veterinary Sciences, James Cook University, Cairns, Australia

Under the Global Programme to Eliminate Lymphatic Filariasis (LF), American Samoa conducted seven rounds of mass drug administration (MDA) from 2000-2006. The WHO recommends post-MDA surveillance using Transmission Assessment Surveys (TAS). Recent studies have suggested TAS may not be sufficiently sensitive for post-MDA surveillance in low antigen (Ag) prevalence settings. We compared the effectiveness of two surveys for post-MDA surveillance: a systematic school-based TAS of Grade 1 and 2 children (mostly aged 6-7 years) in all elementary schools (N=29) and a community-based cluster survey in 28 villages of people aged ≥8 years on the two main islands of American Samoa. Blood samples were collected from each participant, and tested for circulating filarial Ag using the Alere™ Filariasis Test Strip. We estimated crude and adjusted Ag prevalence for both surveys, and evaluated the utility of the school-based survey for identifying villages with high Ag prevalence, using threshold ranging from 1% to 20%. The school-based TAS (n=1143) identified 9 Ag-positive children in 5 schools with adjusted Ag prevalence of 0.7% (95% CI 0.3-1.8), of whom one was microfilaria (Mf) positive. The community-based survey (n=2507, 711 households) identified 102 Ag-positive people with adjusted Ag prevalence of 6.2% (95% CI 4.5-8.6), and Mf prevalence of 25.6% in Ag-positive persons. School-based TAS had limited sensitivity (range 0-23.8%) but high specificity (range 83.3-100%) and positive predictive value (range 0-100%) for identifying villages with high Ag prevalence. American Samoa failed the school-based TAS, and the community-based survey identified higher than expected numbers of Ag-positive people. School-based TAS was logistically simpler, but results were not indicative of the overall Ag prevalence in older persons. The community-based survey was operationally more challenging, but as countries reach elimination targets established by the Global Programme, consideration should be given to testing older persons, including opportunistic and cost-effective methods of screening community members.

1941

POST-ELIMINATION SURVEILLANCE OF LYMPHATIC FILARIASIS IN SRI LANKA: CAN SEX- AND AGE-STRATIFIED CASE DATA BE USED TO DEMONSTRATE TRANSMISSION INTERRUPTION?

Emma L. Davis[1], Joaquin Prada[2], Indeewarie Gunaratna[3], Deirdre Hollingsworth[4]

[1]University of Warwick, Coventry, United Kingdom, [2]University of Surrey, Surrey, United Kingdom, [3]Anti Filariasis Campaign, Ministry of Health, Colombo, Sri Lanka, [4]Big Data Institute, University of Oxford, Oxford, United Kingdom

The Global Program for Eliminating Lymphatic Filariasis (GPELF) was launched in 2000 by the World Health Organization. Initially 81 countries were identified as endemic for LF, but substantial progress has been

made, with 11 countries has successfully completed WHO recommend strategies and awaiting validation and 10 countries validated as having eliminated LF as a public health problem, including Sri Lanka. Following elimination validation in 2016, the Sri Lanka Anti Filariasis Campaign has still been detecting remaining cases in localised areas. Moving from mass drug administration (MDA) to intensive surveillance is a paradigm shift, with very little global precedent to guide the best approach. Developing improved methods for case detection and data interpretation will be a key factor in the drive towards total elimination and during this process it is important to understand whether cases arising through enhanced surveillance represent ongoing transmission or the presence of routinely missed individuals from previous MDA programs. Results from analysis of five years of post-intervention data from the Sri Lanka Anti Filariasis Campaign demonstrate a drastic difference between the age-distribution of cases in males and females, with the majority of cases found in older adult males. Mathematical modelling methods are used to disentangle the probability of ongoing transmission and the burden of residual cases, enabling vital insights into the state of LF transmission in Sri Lanka. We find that the majority of cases represent residual infections that may have been missed by previous programs or resulted from non-adherence to treatment, particularly in adult males, although there is some evidence of ongoing transmission in specific regions, such as Galle. We conclude that total elimination of LF in Sri Lanka should be achievable, but may require intensive effort in regions with higher case incidence.

1942

LYMPHATIC FILARIASIS ELIMINATION IN NEPAL: IDENTIFYING THE BARRIERS AND SOLUTIONS FOR THE LAST MILE

Pradip Rimal[1], Bibek K. Lal[1], Sudip R. Khatiwada[2], Achut B. Ojha[2], Dharmpal P. Raman[2], Joshua Sidwell[3], Michael French[4], Molly Brady[4]

[1]Epidemiology and Disease Control Division, Ministry of Health, Kathmandu, Nepal, [2]RTI International, Kathmandu, Nepal, [3]RTI International, Durham, NC, United States, [4]RTI International, Washington, DC, United States

Sixty-one of Nepal's 75 districts, covering 25 million people, are endemic for Lymphatic Filariasis (LF). Mass drug administration (MDA) with DEC and Albendazole started in 2003; by 2018, all districts had implemented six rounds. To date, 37 districts achieved stop-MDA criteria according to WHO guidelines, of which 19 passed the second transmission assessment survey (TAS II) and five passed TAS III. All 24 districts still requiring treatment should be under post-treatment surveillance by 2021. The program has experienced many challenges: 14 districts have failed Pre-TAS and/or (re)-Pre-TAS, one district failed TAS I, and one district failed TAS II. The program is working to overcome the challenges. Coverage surveys conducted in 2011, 2015, and 2017 and an LF Experts' Meeting in March 2018 identified barriers to high treatment. These include treatment in urban areas, compliance issues in minority populations, variability in sub-district coverage, lack of directly-observed treatment, and fear of side-effects (68% of those non-compliant reported this reason). To overcome these, Nepal has implemented media orientation at the district and central level so health journalists understand the campaign, developed comprehensive SAE management plans at village level, and is developing district-specific activities to improve coverage. Banke district, which has failed (re)-Pre-TAS, is addressing low coverage, particularly in the minority Tharu and Muslim communities and in urban areas. This is done using sub-district level data for planning, mobilizing health workers in addition to volunteers as they are more trusted to respond to adverse events, and community-focused activities like orienting target groups, culturally-appropriate MDA messaging for religious leaders, and community videos of people with LF. Health workers mobilized in 14 low coverage communities directly observed treatment. These resulted in a coverage increase of 13.7% (range; 1.2% - 25.6%) from the previous year. Lessons from this approach can be useful in special community settings with low coverage, and for other countries looking to address coverage issues.

1943

PROGRESS IN STOPPING MASS DRUG ADMINISTRATION FOR ONCHOCERCIASIS - A REPORT FROM THE CARTER CENTER

Emily Griswold[1], Emmanuel Miri[2], Moses Katabarwa[1], Peace Habomugisha[3], Zerihun Tadesse[4], Mauricio Sauerbrey[5], Nabil Aziz[6], Abel Eigege[2], Lindsay Rakers[1], Lauri Hudson-Davis[1], Frank Richards[1]

[1]The Carter Center, Atlanta, GA, United States, [2]The Carter Center, Jos, Nigeria, [3]The Carter Center, Kampala, Uganda, [4]The Carter Center, Addis Ababa, Ethiopia, [5]Onchocerciasis Elimination Program of the Americas, Guatemala City, Guatemala, [6]The Carter Center, Khartoum, Sudan

The Carter Center (TCC) has assisted ministries of health in their fight against onchocerciasis through community-based distribution of Mectizan® (ivermectin) in Africa and the Americas since 1996 To date, the total exceeds 320 million treatments supported across ten countries. This effort has been primarily characterized by expansion. TCC's programs only reached 3.9 million people in 1996; they hope to reach 41 million in 2018, more than a ten-fold increase in scope. Programs hope to provide 73.4 million ivermectin treatments in 2018, in a combination of annual, semi-annual, and quarterly distributions. Much of this increase is due to a change from once- to twice-per-year mass drug administration (MDA) as African programs shifted from control of onchocerciasis to elimination of transmission. The geographic extent has expanded as well, beginning with 109 implementation units (IUs—districts or *Foci*) in 1996 and growing to 260 in 2018. Remarkably, 17% of these units—including four countries—no longer require treatment because they have demonstrated, according to WHO guidelines, that they have either interrupted or eliminated transmission of onchocerciasis. More than 6 million people no longer need treatment. They hail from Nigeria (2.6 million), Uganda (1.9 million), Ethiopia (1.1 million), Guatemala (196,000), Sudan (190,000), Mexico (170,000), Venezuela (107,000), Ecuador (26,000), and Colombia (1,500). While this is the largest number of treatments stopped for onchocerciasis by a non-governmental development organization to date, it represents only 15.3% of the people targeted by TCC-assisted programs. Studies to determine whether treatment may be stopped are pending in three countries (Ethiopia, Nigeria, and Uganda). Activities must focus on determining which areas under MDA can undergo large-scale "Stop MDA" surveys, both in terms of assessing progress and in determining the unit of evaluation.

1944

REVAMPING THE STRATEGY FOR MASS DRUG ADMINISTRATION FOR LYMPHATIC FILARIASIS IN URBAN METROPOLITAN AREAS OF PORT AU PRINCE, HAITI

Alain Javel[1], Carl Fayette[1], Franck Monestime[1], Eurica Denis[1], Ellen Knowles[2], Sarah Craciunoiu[2], Cudjoe Bennett[2], Jean-Frantz Lemoine[3], Abdel Direny[4]

[1]IMA World Health, Port-au-Prince, Haiti, [2]IMA World Health, Washington, DC, United States, [3]National Program to Eliminate Lymphatic Filariasis, Ministry of Public Health and Population, Port-au-Prince, Haiti, [4]RTI International, Washington, DC, United States

To achieve global goals to eliminate lymphatic filariasis (LF), the Haiti NTD Control Program (HNTDCP) follows WHO's recommendations to implement rounds of annual mass drug administration (MDA) of diethylcarbamazine and albendazole for at least five consecutive years among at risk populations to halt LF transmission by 2020. In 2018, 84% of the 140 communes are under surveillance. Among the 23 communes that have not achieved the criteria for stopping MDA, five are in the densely populated Port au Prince metropolitan area where MDA coverage has declined each year since 2012; from an average of 86% to 44% by 2017. Two surveys were conducted after the 2017 MDA: use of the supervisor's coverage tool in Tabarre commune and a social mobilization survey in a neighboring commune (Croix des Bouquets). With these results, HTNDCP and its partners organized a workshop to analyze the situation and adopt improved strategies tailored for the urban setting to improve

coverage. During microplanning meetings, coverage zones were mapped and previous distribution posts were geolocalized, which identified gaps in supervision areas, while others overlapped. As a result, visibility and access to the drugs will be improved by increasing the pool of community volunteers with updated communication materials. One additional day has been added to the four distribution days with timing adjusted to catch hours of high foot traffic. Going forward, the community sensitization will be intensified with revamped IEC messages including TV and radio spots, which have been tested by focus groups and then modified. Supervision will be reinforced with clear plans (random and purposive selection of distribution posts) and tailored tools. Data collection tools have been updated to facilitate rapid daily reporting for key indicators and mobile technology will be used for real time reporting. Further, a hotline will be available to respond to community questions and help with side effect management and referrals. HNTDCP and its partners expect improved coverage during the April and May 2018 MDA with results expected in June 2018.

1945

IMPACT OF ENHANCED MDA WITH DEC PLUS ALBENDAZOLE FOR ELIMINATION OF LYMPHATIC FILARIASIS IN COASTAL GALLE DISTRICT, SRI LANKA

Indeewarie E. Gunaratna[1], Dammika de Mel[1], Gowri J. De Silva[1], Tharanga D. Dassanayake[1], Manjula W. Punchihewa[2], Channa T. Yahathugoda[3], Ramakrishna Rao[4], Mirani V. Weerasooriya[3], Gary J. Weil[4], Devika Mendis[1]

[1]Anti-Filariasis Campaign, Ministry of Health, Colombo, Sri Lanka, [2]Regional Anti-Filariasis Unit, Ministry of Health, Galle, Sri Lanka, [3]Faculty of Medicine, University of Ruhuna, Galle, Sri Lanka, [4]Washington University School of Medicine, St. Louis, MO, United States

The Sri Lankan Anti-Filariasis Campaign (AFC) distributed 5 rounds of MDA (DEC/ALB) according to WHO guidelines to some 10 million people in 8 endemic districts between 2002 and 2006. Sri Lanka met WHO validation criteria for elimination of lymphatic filariasis (LF) as a public health problem in 2016. Comprehensive post-MDA surveys identified areas in coastal areas in Galle district with low-level persistence of LF. AFC distributed additional rounds of MDA in 2014 and in 2015 to 14 of 20 MOH areas in Galle (target population 850,000) with relatively moderate coverage (~78%), but this failed to eliminate the infection. In 2016 AFC provided one round of enhanced MDA (eMDA) in 11 MOH areas with participation of more than 3000 people from the Ministry of Health, private and public institutions, and volunteers. Intensive social mobilization and awareness activities (SMS, media, flyers, meetings) were conducted prior to MDA. Approximately 600,000 people aged ≥ 2 yr in 11 MOH areas were targeted, and MDA was provided over 2 days. AFC reported excellent MDA and DOT compliance rates of 90% and 47%, respectively. An independent assessment based on 1100 persons surveyed in 30 clusters found MDA and DOT compliance rates of 89% and 37%. Understanding the purpose of MDA was significantly correlated with drug consumption ($P < 0.001$). 7% of the surveyed population reported mild or moderate adverse events after treatment. Limited molecular xenomonitoring (MX) studies performed before and after eMDA showed a trend toward reduced parasite DNA rates in mosquitoes, but this was not statistically significant: maximum likelihood filarial DNA rates were 1.3%, CI 1.0-1.5 before MDA and 0.92%, CI 0.7-1.2 after MDA. These rates are higher than our provisional MX target for LF elimination (0.25%, upper CI 1%). These results show that eMDA can lead to very high measured compliance, but the MX results suggest that a single round of eMDA may not be sufficient to reach true elimination of LF across the evaluation unit. AFC has increased test and treat activities and other interventions to clear infections in remaining problem areas.

1946

LYMPHATIC FILARIASIS ELIMINATION IN URBAN AFRICA: MICRO-STRATIFICATION OVERLAP MAPPING, RISK DELINEATION AND TRANSMISSION ASSESSMENT SURVEYS

Upendo Mwingira[1], Maria Chikawe[1], Cecilia Uisso[1], Wilfred Mandara[1], Alpha Malishee[1], Mwele Malecela[2], Mark Taylor[3], Hayley E. Mableson[3], Louise A. Kelly-Hope[3]

[1]National Institute of Medical Research, Tanzania, Dar es Salaam, United Republic of Tanzania, [2]WHO Regional Office for Africa, Brazaville, Republic of the Congo, [3]Department of Parasitology, Liverpool School of Tropical Medicine, Liverpool, United Kingdom

The city of Dar-es-Salaam in Tanzania has a significant risk of lymphatic filariasis (LF), which is transmitted by *Culex* spp. mosquitoes that thrive in poor human domestic environments. At the start of the National LF Elimination Programme, the overall infection rate was ~10%, with nearly double the risk found in informal settlements and peri-urban areas. Since 2013, mass drug administration (MDA) with ivermectin and albendazole has been scaled up successfully, and many areas of the city have reached high coverage rates and significant reductions in prevalence. The National LF programme is preparing to scale down MDA and planning to implement Transmission Assessment Surveys (TAS) in selected low risk areas. Identifying low risk areas to start TAS will be challenging in such a large dynamic city. The aim of this study was to use programmatic data together with satellite imagery and remote sensing data to categorise the different areas of the city into risk zones. All LF sero-prevalence, morbidity data, MDA distribution points and treatment coverage rates were georeferenced and mapped at ward and/or health centre level. Firstly, micro-stratification mapping methods and programmatic data were used to develop composite maps and risk categories as i) high LF risk/low MDA coverage ii) high LF risk/high MDA coverage iii) low LF risk/low MDA coverage and iv) low LF risk/high MDA coverage. Secondly, high resolution satellite imagery, and topographical and population maps were used to further delineate risk across the city and within these categorised areas to help ensure that the future scaling down of MDA is successful. The results of this study will reduce the population and geographical area at risk, and also help to optimise resources by targeting interventions to where they are needed most.

1947

RETHINKING ELIMINATION STRATEGIES FOR LYMPHATIC FILARIASIS TRANSMISSION HOT SPOTS IN HAITI

Carl Fayette[1], Alain Javel[1], Franck Monestime[1], Eurica Denis[1], Ellen Knowles[2], Sarah Craciunoiu[2], Cudjoe Bennett[2], Jean-Frantz Lemoine[3], Abdel Direny[4], Abdel Direny[4]

[1]IMA World Health, Port-au-Prince, Haiti, [2]IMA World Health, Washington, DC, United States, [3]National Program to Eliminate Lymphatic Filariasis, Ministry of Public Health and Population, Port-au-Prince, Haiti, [4]RTI International, Washington, DC, United States

Based on baseline mapping (2000/2001) in Haiti, lymphatic filariasis (LF) was determined to be endemic throughout the country. Ninety percent of 140 total communes had low prevalence (below 4.5%), while 15 communes, categorized as "red zone," had prevalence ranging from 10 to 45%. While there has been significant progress to date, with 85% of communes in post-MDA surveillance phase, LF transmission still persists in a total of 14 communes in the red zone, including Arcahaie, Cabaret, and Croix des Bouquets in the West department. In order to conduct a transmission assessment survey (TAS), WHO guidance recommends at least 5 MDA rounds of > 65% coverage of total population and sentinel and spot-check site results with < 2% antigenemia. Sentinel and spot-check site surveys in 2015 found continued high antigenemia prevalence of 41%, 8.1% and 8.7% in Arcahaie, Cabaret and Croix des Bouquets, respectively; therefore, the MDA in 2016 and 2017 was changed to increase social mobilization in those sites with >2% prevalence. However, in 2017 repeated sentinel and spot-check sites still found more than 20%

antigenemia in Arcahaie and 8% in Cabaret and Croix des Bouquets. MDA coverage has been decreasing over the years and by 2017, coverage was marginal in Croix des Bouquets (median: 68) and Arcahaie (median: 57). These results underline a need for improved strategies. In North department, a triple drug study is being carried out in select red zone communes and could be considered in these communes per 2017 WHO guidelines. Additionally, pre-TAS results suggest a need for a more targeted MDA approach followed by a mini-TAS in the hot spot zones. This can include conducting a microplanning exercise to identify challenges and missed opportunities to improve access to MDA, generate demand and support communes through better tools (supervisor checklists and guidelines) as a way to increase the coverage rate in the hot spot areas.

1948

ADVERSE EVENTS FOLLOWING SINGLE DOSE TREATMENT OF LYMPHATIC FILARIASIS: OBSERVATIONS FROM A REVIEW OF THE LITERATURE

Philip Budge, Carly Herbert, Britt Andersen, Gary Weil

Washington University in St. Louis, St. Louis, MO, United States

WHO's Global Programme to Eliminate Lymphatic Filariasis (LF) uses mass drug administration (MDA) of anthelmintic medications to interrupt LF transmission in endemic areas. It has recently been shown that a single dose combination of ivermectin (IVM), diethylcarbamazine (DEC), and albendazole (ALB) is markedly more effective than the standard two-drug regimens (DEC or IVM, plus ALB) for achieving long-term clearance of microfilaremia. This IVM/DEC/ALB triple therapy (IDA) has been approved by WHO for programmatic use after large safety studies found equivalent rates and severity of adverse events with IDA compared to DEC/ALB. To provide context for the results of the IDA safety studies, we searched Ovid Medline for studies published from 1985 - 2017 that reported adverse events (AEs) following treatment of LF with IVM, DEC, ALB, or any combination of these medications. Studies that reported AE rates by treatment group were included. We reviewed 162 published manuscripts, 55 of which met inclusion criteria. Among these, 34 were clinic or hospital-based clinical trials, and 21 were community-based studies. Reported AE rates varied widely. The median AE rate following DEC or IVM treatment was greater than 60% among microfilaremic participants and less than 10% in persons without microfilaremia. The most common AEs reported were fever, headache, myalgia or arthralgia, fatigue, and malaise. Mild to moderate systemic AEs related to death of microfilariae are common following LF treatment. Post-treatment AEs are transient and rarely severe or serious. Comparison of AE rates from different community studies is difficult due to inconsistent AE reporting, varied infection rates, and varied intensity of follow-up. A more uniform approach for assessing and reporting AEs, such as that outlined in the CONSORT checklist for reporting harms in clinical trials, applied to LF community treatment studies would be helpful.

1949

EVALUATING THE IMPACT OF 17 YEARS OF ANNUAL IVERMECTIN MASS DRUG ADMINISTRATION IN THE MAHENGE ONCHOCERCIASIS TRANSMISSION FOCUS IN TANZANIA

Andreas Nshala[1], Maria Chikawe[2], Cecilia Uisso[2], Oscar Kaitaba[2], Sarah Craciunoiu[3], Paul Cantey[4], William Kisoka[5], Mathias Kamugisha[5], Upendo Mwingira[2]

[1]IMA World Health, Dar es Salaam, United Republic of Tanzania, [2]Tanzania Neglected Tropical Disease Control Program, Dar es Salaam, United Republic of Tanzania, [3]IMA World Health, Washington, DC, United States, [4]World Health Organization, Geneva, Switzerland, [5]National Institute for Medical Research, Dar es Salaam, United Republic of Tanzania

The Tanzania NTD Control Program's (TZNTDCP) goal is to eliminate onchocerciasis (OV) by 2025 in line with World Health Organization (WHO) targets, and as guided by the updated WHO guidelines for OV elimination. OV is endemic in seven *Foci* across 28 districts in six regions in Tanzania. By 2017, all districts had received 10 to 17 rounds of Ivermectin mass drug administration (MDA) with effective coverage. Four districts in Morogoro region make up the Mahenge focus area. In 2017 in Mahenge focus, the TZNTDCP evaluated the impact of 17 rounds of annual ivermectin MDA in the four districts by surveying the prevalence of OV among children <10 years old. Purposively, a total of 7 first-line villages (that are close to the known simulium breeding sites) were selected. At each village, the sampling universe was constructed from household registers for systematic sampling. A total of 1799 children were tested using the OV16 RDT that detects IgG4 antibodies against the Ov16 antigen in human blood samples. Dry blood spots were also collected for further OV16 ELISA testing. OV16RDT tests were completed in the field following manufacturer guidelines and results were provided to participants immediately. Prevalence of positive OV16 RDT tests ranged from 0%-5.8% across all test sites. Overall 33 out 1799 children tested were positive. Mgugwe and Uponera villages reported the highest (5.8% and 4.1% positive children respectively). These results indicate an ongoing transmission of infection among the communities as children born well after the treatment program started are still being infected. While there remains a need to investigate the validity of high reported MDA treatment coverage and the status of infection in the vectors (black flies), the OV16 ELISA testing will take place in June 2018 and these results will further inform the program on proper strategies to accelerate OV elimination for all OV endemic districts in Tanzania.

1950

COST-EFFECTIVENESS OF INTEGRATED VECTOR CONTROL FOR LYMPHATIC FILARIASIS ELIMINATION IN TAMIL NADU, INDIA

Donald S. Shepard[1], Aung K. Lwin[1], Sunish I. Pulikkottil[2], Mariapillai Kalimuthu[3], Natarajan Arunachalam[3], Brij K. Tyagi[3], Graham B. White[4]

[1]Brandeis University, Waltham, MA, United States, [2]Indian Council on Medical Research, Port Blair, India, [3]Indian Council on Medical Research, Madurai, Tamil Nadu, India, [4]University of Florida, Gainesville, FL, United States

Vector control is a potentially effective intervention to augment annual mass drug administration (MDA) towards the elimination of lymphatic filariasis. We conducted cost-effectiveness analysis of MDA alone and augmented by VC using data from a cluster randomized trial and historical controls. We built on an effectiveness trial. It randomized 36 villages in the State of Tamil Nadu, India, at risk of LF transmission into three groups of 12 villages each: MDA alone (the standard of care); MDA plus expanded polystyrene beads (MDA+EPB) for covering the water surface in wells and cesspits to suppress the filariasis vector mosquito Culex quinquefasciatus; MDA plus integrated vector control combining EPB with insecticidal pyrethroid impregnated curtains (MDA+EPB+PIC) over windows, doors, and eaves. Economic costs in 2010 US$ combined village and higher levels. Outcomes were antigen prevalence (AGP), microfilaria prevalence below the level for elimination (MFP<1%) from 2010 to 2013, and modeled Disability Adjusted Life Years (DALYs). The estimated annual cost per village resident was US$0.53 for MDA alone, US$1.02 for MDA+EPB, and US$1.83 for MDA+EPB+PIC. MDA and MDA+EPB+PIC increased the percentages of villages with MFP<1% by 67% and 75% of villages, respectively, although not statistically significant. The resulting incremental cost-effectiveness ratios per DALY averted were $7.2 and $141, respectively. The findings confirm that both MDA and MDA+EPB+PIC are both effective and very cost-effective strategies for eliminating LF. As MDA alone lowered MFP substantially and AGP takes years to change, the study had limited power to estimate the incremental benefits of vector control. While MDA+EPB+PIC costs three times as much as MDA alone, its substantially greater effectiveness makes it more cost-effective. This VC combination accelerates LF elimination by about one year and may contribute to LF elimination in defined communities.

1951

THE RELATIVE SAFETY OF A PROMISING TRIPLE DRUG MASS DRUG ADMINISTRATION REGIMEN VERSUS A TWO-DRUG REGIMEN FOR LYMPHATIC FILARIASIS ELIMINATION IN INDIA

Jambulingam Purushothaman[1], Vijesh Sreedhar Kuttiatt[1], Subramanian Swaminathan[1], Krishnamoorthy Kaliannagounder[1], Srividya Adinarayanan[1], Gary J. Weil[2]

[1]ICMR-Vector Control Research Centre, Puducherry, India, [2]Washington University School of Medicine, St. Louis, MO, United States

India launched a programme to eliminate lymphatic filariasis (LF) in 256 endemic districts in 2004 with annual mass drug administration (MDA) of a single dose of diethylcarbamazine with albendazole (DA). Since more than 50% of these districts have not met elimination targets despite more than 10 rounds of MDA, new strategies are needed if LF is to be eliminated by 2020. Recent clinical trials have shown a single dose of ivermectin with DA (IDA) is superior to DA for clearing microfilaremia (Mf). As part of a multicentre study, our group conducted a community-based study in an endemic district in Karnataka state to compare the safety and efficacy of IDA with DA. Pre-intervention filarial antigenemia (Ag) and Mf prevalence were 25% and 6%, respectively in the study area despite 12 prior rounds of MDA with DA. Treatment assignment was randomized by village, and consenting residents >5 years of age were treated with IDA (4782) or DA (4273). Adverse events (AE) were actively assessed by house-to-house follow-up of participants for 2 days followed by passive follow-up for an additional 5 days. More than 90% of participants had active follow-up on days 1 and 2. AEs were significantly more frequent after IDA (8%) than after DA (6.2%). AEs were more frequent in females (8.6%) than in males (5.5%), and this was independent of age. As expected from prior treatment studies, AE rates were much higher in participants with Mf and higher after IDA (40%) than after DA (20%). Most AEs were mild after IDA (90.3%) and DA (97.7%). The most common AEs were fever, headache, dizziness, nausea, vomiting and fatigue. All AEs were self-limiting or resolved after simple symptomatic treatment. There were no serious AEs, and no participant required hospitalization. One participant had severe diarrhoea that started 6 days after IDA, but this was not considered to be treatment related. Thus, while AEs were more common after IDA (especially in Mf positives), our results suggest that IDA is safe and feasible for use as a MDA regimen in India to hasten LF elimination.

1952

FIELD IMPLEMENTATION OF A NOVEL TOOL FOR THE COLLECTION OF MOSQUITO EXCRETA AND FECES FOR THE MOLECULAR XENOMONITORING OF FILARIAL WORMS AND MALARIA IN GHANA

Corrado Minetti[1], Nils Pilotte[2], Darren Cook[1], Mike Yaw Osei-Atweneboana[3], Steven A. Williams[2], Lisa J. Reimer[1]

Current molecular xenomonitoring methods for the detection of parasites such as filarial worms require processing large numbers of mosquitoes, resulting in increased time, cost and labour required. Screening the mosquito excreta/faeces (E/F) rather than whole carcasses allows for a higher throughput by removing the need to discriminate vector species, since also non-vectors release ingested pathogens and their DNA in E/F, and sensitivity of detection, enabling larger numbers of mosquitoes to be processed per pool. We recently developed a superhydrophobic cone allowing for the efficient collection of E/F from live mosquitoes. We performed the first field implementation of this tool in two endemic rural communities in Ghana to assess its applicability in determining the presence of filarial worms and malaria parasites in the community. The presence of parasite DNA was compared between mosquito E/F and whole insects, and to parasitological detection in human blood via rapid diagnostic tests, microscopy and real time PCR. We successfully detected the presence of filarial and malaria parasites in mosquito E/F as well as in mosquito carcasses, and we also reported the presence of the midge-borne filarial parasite *Mansonella* in both E/F and a large number of people. In this talk, we will also present the relationships between parasite positivity in the E/F and mosquito carcasses and human samples. Detection of pathogen DNA in mosquito excreta on the field is possible even for parasites which are not vectored by mosquitoes, and this approach represents a new and promising molecular xenomonitoring tool.

1953

HUMORAL IMMUNE RESPONSE INDUCED BY HELMINTH AND MALARIA PARASITE COINFECTION IN CENTRAL GHANA

Dennis Adu-Gyasi[1], Seth Owusu-Agyei[2], Margaret T. Frempong[3], Dennis Konadu Gyasi[1], David Dosoo[1], Jones Opoku-Mensah[1], Rupert Delmini[2], Ben Gyan[4], Kwaku Poku Asante[1]

[1]Kintampo Health Research Centre, Kintampo North, Ghana, [2]University of Health & Allied Sciences, Ho, Ghana, [3]Kwame Nkrumah University of Science and Technology, Kumasi, Ghana, [4]Noguchi Memorial Institute for Medical Research, Accra, Ghana

Factors from the environment and host characteristics affect the immune response elicited by host to helminth and malaria parasite co-infection in endemic area. We studied the humoral immune response by helminths and malaria infection in the middle-belt of Ghana, West Africa. Cross-sectional community survey of 1826 participants were randomly recruited at household level. Biological samples were collected over 12-month period. ELISA techniques were employed to estimate the concentrations of immunoglobulins (IgG, IgG1 and IgM) in the plasma using crude parasite antigens and also with BD Cytometric Bead Array (CBA) for IL-2, IL-4, IL-6, IFN-γ, TNF-A and IL-5. From supernatant of PBMCs cultured with *Pf parasitized RBCs*, BD CBA Human Thl/Th2/Th17 Cytokine kit was used to estimate cytokine (IL-2, IL-4, IL-6, IFN-γ, TNF-A, IL-17A, and IL-10) concentration using the BD LSRFORTESSA X20. Concentration of IgG to *NF54* antigens (p=0.007) and IgG to hookworm antigens (p=0.018) were significantly different among no infection, helminth, malaria, and helminth-malaria co-infected in the study. Concentrations of plasma cytokines TNF-A (p=0.007), IL-4 (p=0.01), IL-5 (p=0.009) and IL-6 (p<0.0001) were significantly different when compared among the infection status of participants. From the culture supernatant, compared to those with no infection, IL-6 was significant among hookworm-malaria co-infected (p=0.011). IL-4 concentration was different among the various infection groups (p=0.021) and the significant difference was between hookworm and hookworm-malaria co-infected then malaria and hookworm-malaria co-infected individuals. Hookworm infection increased significantly IgG1 concentration with malaria parasite crude antigen. IgG1 to hookworm cross-react with *Pf* parasite antigens. In hookworm infected individuals, IL-17A correlates with IL-6, IL-10, and IFN-gamma. Also, pro-inflammatory cytokines positively correlate in hookworm infection. Among individuals infected with malaria, upon exposure to malaria antigens, they unpredictably induce IL-4 cytokine.

1954

MOLECULAR EPIDEMIOLOGY OF *ANISAKIS SPP.* IN BLUE WHITING *MICROMESISTIUS POUTASSOU* IN EASTERN WATERS OF SPAIN, WESTERN MEDITERRANEAN SEA

Dolores Molina-Fernández, Daniel Rubio-Calvo, Francisco Javier Adroher, Rocío Benítez

Departamento de Parasitología, Facultad de Farmacia, Universidad de Granada, Granada, Spain

The infection of blue whiting *Micromesistius poutassou* from the western Mediterranean Sea, off the eastern coast of Spain, with larvae of *Anisakis* spp. was studied. Between April 2016 and April 2017, 140 fish were analyzed. Total epidemiological data showed that the prevalence of *Anisakis* spp. was 29.3% and the mean intensity 1.8. Of the 74 larvae

collected, 60.8% were type I and the remaining 39.2%, type II. Of the former, 91.1% were molecularly identified as *Anisakis pegreffii* (P=19.3%; MI=1.4), 2.2% as *Anisakis simplex s.s.* (P=0.7%; MI=1.0), while the rest (6.7%) showed a recombinant genotype between the two (P=2.1%; MI=1.0). All the type II larvae analyzed were molecularly identified as *Anisakis physeteris* (P=10.0%; MI=2.1). Only three fish (2.1%) were found to have larvae in the muscle, while two were found with 1 larva of *A. pegreffii* and one with two larvae (1 *A. simplex s.s.* and 1 *A. pegreffii*). Statistical analysis showed that the prevalence of *Anisakis* spp. in blue whiting is higher in spring than in autumn (p<0.001), probably due to the greater size (and age) of the fish then related with factors as diet shift, accumulation with age, higher food intake. On the other hand, the analysis of the data suggests that blue whiting is first infected with *Anisakis* type I (mean age 2.3 years) and later with *Anisakis* type II (mean age 2.7 years), probably due to the diet of the blue whiting with age, incorporating into its diet the paratenic/intermediate host species of these parasites. In any case, the public health authorities must continue to emphasize the need for suitable thermal treatment (freezing or cooking) of the fish prior to consumption. Funded by Spanish State Research Agency and European Regional Development Fund (ERDF) [grant number CGL2013-47725-P]

1955

ANTHELMINTIC TREATMENT RESPONSE AND EMERGENCE OF ANTHELMINTIC RESISTANCE IN HUMAN POPULATION OF SOUTHERN MOZAMBIQUE INFECTED WITH SOIL-TRANSMITTED HELMINTHS

Berta Grau-Pujol[1], Maria Martinez-Valladares[2], Jorge Cano[3], Anelsio Cossa[4], Charfudin Sacoor[5], Jose Muñoz[6]

[1]Institut de Salut Global de Barcelona (ISGlobal); Centro de Investigação em Saúde de Manhiça (CISM), Mozambique; Fundación Mundo Sano, Argentina, Vila de Manhiça, Mozambique, [2]Instituto de Ganadería de Montaña (CSIC-Universidad de León), Department of Animal Health, Leon, Spain, [3]London School of Hygiene & Tropical Medicine, London, United Kingdom, [4]Centro de investigação em Saúde da Manhiça (CISM), Vila de Manhiça, Mozambique, [5]Centro de Investigação em Saúde de Manhiça (CISM), Vila de Manhiça, Mozambique, [6]Institut de Salut Global de Barcelona (ISGlobal); Centro de Investigação em Saúde de Manhiça (CISM), Mozambique, Barcelona, Spain

Over one billion people are infected with soil-transmitted helminths (STH) worldwide, nearly a quarter of the world population. STH infections (*Ascariasis lumbricoides*, *Trichuris trichiura*, hookworm and *Strongyloides stercoralis*) can contribute to anemia, malnutrition, and delayed development among others. The cornerstone for controlling STH is mass drug administration (MDA) programs with benzimidazole drugs. However, several factors limit this strategy: low coverage, high re-infection rates and low efficacy against some STH infections (e.g. *T. trichiura* and *S. stercoralis*). Furthermore, since STH MDA strategy is a monotherapy, benzimidazole resistance emergence is a concern. The aim of this study was to design and implement a pilot surveillance platform for the genotypic and phenotypic characterization of anthelminthic resistance to albendazole in Manhiça district, Southern Mozambique. We conducted a cross-sectional study in Manhiça district where we recruited 400 people older than 15 years of age censed in Centro de Investigação em Saúde da Manhiça Demographic Surveillance System. We used grid sampling methodology to obtain spatial representativeness. Two stool samples from two consecutive days were collected from every participant. Regarding STH infection positive participants, a third and a forth stool samples were collected a day before and twenty-one days after treatment respectively. Stool samples were analyzed by Telemann concentration technique and Kato-Katz thick smear technique. A proportion of 21% of participants were infected with at least one STH. Phenotypic albendazole resistance will be detected by cure rate and egg reduction rate. Genotypic albendazole resistance will be evaluated by pyrosequencing, in order to detect mutations in the beta-tubulin gen related with anthelmintic resistance to benzimidazole drugs. The SaTScan method will be employed for identification of pockets of risk and clustering of STH infection and albendazole resistance. Krieging will be used to estimate general spatial trends in infection. Final results are still under analysis.

1956

SCHISTOSOMIASIS AND SOIL-TRANSMITTED HELMINTHS IN TWO HEALTH DISTRICTS OF THE KWILU PROVINCE, DEMOCRATIC REPUBLIC OF THE CONGO: EVALUATION OF THE PREVALENCE AMONG SCHOOLCHILDREN AND IN THE COMMUNITY

Raquel Inocencio da Luz[1], Clementine Roucher[1], Sylvie Linsuke[2], Epco Hasker[1], Katja Polman[1], Marleen Boelaert[1]

[1]Insitute of Tropical Medicine, Antwerp, Belgium, [2]Institut National de Recherche Biomédicale, Kinshasa, Democratic Republic of the Congo

Schistosomiasis (SCH) and soil-transmitted helminths (STH) control relies on Mass Drug Administration (MDA) campaigns and the World Health Organization (WHO) promotes a school-based strategy. Epidemiological data for the Democratic Republic of the Congo (DRC) are rather scarce to adequately plan MDA campaigns. We conducted two prevalence surveys to provide estimates of the disease burden. Both surveys were conducted in the Health Districts of Mosango and Yasa Bonga, Kwilu province, DRC. First, school children were surveyed in 2016 using the WHO recommended methodology. One stool and one urine sample were collected for parasitological examination by Kato Katz and urine filtration technique. Subsequently, a community based survey was held in 2017 using cluster sampling to include young children (1-5years), schoolchildren (6-14years) and adults (>18years). One stool sample was examined. 526 school children enrolled in the school-based survey and results show a *S. mansoni* prevalence of 8.9% (95%CI: 3.5-13.2) in both districts and no *S. haematobium* infection was found. The most prevalent STH infection was hookworm with 52.9% (95%CI: 29.3-62.4) in both districts, followed by *A. lumbricoides* (9.3%; 95%CI: 5.8-15.4) and *T. trichiura* (2.1%; 95%CI: 0.9-4.9). 1652 participants enrolled in the community survey. Preliminary results show that *S. mansoni* infection was not found. For STH, hookworm infection was most prevalent in the population (28.8%; 95%CI:26.7-31.1) followed by *A. lumbricoides* (2.2%; 95%CI:1.5-2.9) and *T. trichiura* (1.5%; 95%CI:0.9-2.1). The distribution of any STH infection was 25,5% in young children, 31,3% in schoolchildren and 35,2% in adults. Based on these results, both districts are categorized as low risk communities for SCH, however, no *S. mansoni* infection was found in the community survey. This could be explained by the disease being clustered in the vicinity of rivers. For STH, both districts need MDA in schoolchildren twice a year. However, preliminary results of the community survey suggest that adults and young children are equally affected by STH. Community-wide MDA seems therefore more suitable in this area.

1957

RISK FACTORS FOR HUMAN HOOKWORM INFECTION IN A TRIBAL POPULATION: RESULTS FROM THE BASELINE SURVEY OF THE DEWORM3 INDIA STUDY SUBSITE

Saravanakumar Puthupalayam Kaliappan[1], Jasmine Farzana[1], Dilip Abraham[1], Malathi Manuel[1], Chinnadurai Pandi[1], Katherine E. Halliday[2], William Oswald[2], Mira Emmanuel-Fabula[3], Sean Galagan[3], Kristjana H. Ásbjörnsdóttir[3], Sitara Ajjampur[1], Gagandeep Kang[1], Judd L. Walson[3]

[1]Christian Medical College, Vellore, India, [2]The London School of Hygiene & Tropical Medicine, London, United Kingdom, [3]University of Washington, Seattle, WA, United States

Global estimates for infection with the soil transmitted helminths (STH), *Ascaris lumbricoides*, *Trichuris trichura*, and hookworm are 819, 464.6 and 438.9 million respectively with 67% of these infections occurring in Asian populations. The DeWorm3 study on testing the feasibility of interrupting STH transmission using bi-annual community-wide MDA compared to

school-age targeted MDA is a multi-country study including a series of cluster randomised field trials. In India, the field trial has 2 subsites, Timiri and Jawadhu Hills in Tamil Nadu. We present the results from baseline surveys of the Jawadhu Hills subsite. This site is a hard to access, hilly tribal area with poor health care and sanitation and with most adults engaged in migrant labour. The subsite has 8 study clusters censused, and has a mean population of 4100 (range 2800-6000) per cluster. Approximately 150 subject in each cluster were randomly selected to participate in a longitudinal monitoring cohort (LMC) in an age stratified manner with 30 preschool age children (PSAC), 30 school age children (SAC) and 90 adults per cluster. A total of 1220 fecal samples collected from participants in the LMC were tested for STH ova by the Kato-Katz test. The prevalence of hookworm in PSAC, SAC and adults was 9.7%, 24.5% and 52.6% respectively. *Ascaris* (4 individuals) and *Trichuris* (1 individual) infections were rare in this community. In a multivariable logistic regression that used generalised estimating equations for risk factor analysis, increasing age and open air defecation were independently associated with hookworm infection (Odds Ratios (OR): 1.03 (95% CI: 1.02-1.04) per year of age and 2.95 (1.46-5.97) respectively). Other risk factors analysed such as not being dewormed, not wearing footwear, availability of soap at hand washing facility and gender were not significantly associated with hookworm infection. Studies on risk factors associated with transmission of STH especially hookworm in these marginalized communities with cultural barriers to the use of toilets are extremely important to formulate effective preventive strategies.

1958

PARASITES DETECTED BY METAGENOMIC BARCODING BOTH CONFIRM MICROSCOPY AND IDENTIFY ADDITIONAL ORGANISMS

Leah A. Owens[1], Sagan Friant[2], Sarah Phillips-Garcia[3], Melissa Emery-Thompson[3], Tony L. Goldberg[1]

[1]University of Wisconsin Madison, Madison, WI, United States, [2]Hunter College- City University of New York, New York, NY, United States, [3]University of New Mexico, Albuquerque, NM, United States

Although microbiome research has led to an explosion of knowledge about prokaryotic communities and their influence on host health, a parallel revolution for eukaryotic communities has yet to be realized. The field of parasitology in particular would benefit from a metagenomic method for characterizing eukaryotes. We used a metagenomic barcoding approach to detect eukaryotic parasites in fecal samples using published pan-eukaryotic primers. After creating a validation set of parasites, we extracted genomic DNA, amplified a common barcode region (18S ribosomal RNA gene), and deep sequenced the amplicon. This approach identified 100% (n=6 helminths, n=6 protozoans) of organisms in the validation sample, 75% (9/12) to the species level and 25% (3/12) to the genus level. We then repeated the process with samples from wild nonhuman primates where matched fecal samples had been previously characterized by microscopy in published studies, adding steps to enrich for parasite DNA. Results were analyzed with a combination of mothur, qiime, and custom python scripts using the SILVA132 database. The percentage of host reads ranged from 2.77% to 5.1% with a mean= 3.79% and median= 3.45%. In one representative sample, 5.24% of filtered reads mapped to a ciliate species found via microscopy and 4.42% mapped to a protozoan not identified by microscopy but expected to be present based on PCR-based diagnostics. This work demonstrates the potential of a metagenomic barcoding approach for identifying eukaryotic gastrointestinal parasites.

1959

POOLING STRATEGY VALIDATION AND PREVALENCE-BASED MODELING FOR COST-EFFECTIVE AND EFFICIENT MONITORING OF SOIL-TRANSMITTED HELMINTH INFECTIONS

Marina Papaiakovou[1], Nils Pilotte[2], Jessica R. Grant[2], James Wright[3], Fabian Schaer[4], Iain Gardiner[4], Raju Misra[1], Judd L. Walson[5], Steven A. Williams[2], Tim Littlewood[1]

[1]Natural History Museum, London, United Kingdom, [2]Smith College, Northampton, MA, United States, [3]Imperial College, London, United Kingdom, [4]Deworm3, Natural History Museum, London, United Kingdom, [5]University of Washington, Seattle, WA, United States

The strategy of pooling stool specimens has been extensively used in the field in order to facilitate the screening of large numbers of samples for the detection of soil-transmitted helminths whilst minimizing the oftentimes prohibitory cost associate with large-scale PCR-based molecular studies. It is important for such a tool to be tailored and standardized to any given study or circumstance in order to be most beneficial. The development and subsequent validation of a standard operation protocol for pooling (with focus on pools of 5) was employed as part of the Deworm3 project, where model-based community-wide mass drug administration is being tested to break transmission of STH infections. Within a recommended confidence, field samples with known real-time PCR results at an individual level were used (strategic pooling) in order to ratify the robustness of the strategy while maintaining the sensitivity and specificity of the real-time PCR assay. A key goal of pooling is to minimize the samples screened and reduce the cost of the overall DNA extraction and real-time PCR testing for the detection of soil-transmitted helminths. However, there are cases where pooling is likely not to be the most practical or time-efficient tactic to follow. In regions/clusters, where the prevalence for a targeted infection is high, the majority of the pools created in the laboratory setting will be positive for that infection. In cases where the focus is on identifying infected individuals within a pool, revisiting individual samples ('spin-outs') in high prevalence areas increases the cost of the DNA extractions and PCR testing significantly. The validation of a robust pooling strategy along with a model that demonstrates cost-effectiveness across different prevalence settings (e.g. as estimated by microscopy) would be beneficial not only for reliable screening and molecular testing at a community level, but will significantly reduce the overall cost as well.

1960

DEWORM3 INDIA STUDY SITE: DESCRIPTION OF THE STUDY POPULATION AND PREVALENCE OF SOIL-TRANSMITTED HELMINTHS

Sitara Ajjampur[1], Saravanakumar Puthupalayam Kaliappan[1], Jasmine Farzana[1], Dilip Abraham[1], Malathi Manuel[1], Rajeshkumar Rajendiran[1], Sridhar Doss[1], Chinnadurai Pandi[1], Katherine E. Halliday[2], William Oswald[2], David Kennedy[2], Mira Emmanuel-Fabula[3], Sean Galagan[3], Kristjana H. Ásbjörnsdóttir[3], Gagandeep Kang[1], Judd L. Walson[3]

[1]Christian Medical College, Vellore, India, [2]The London School of Hygiene & Tropical Medicine, London, United Kingdom, [3]University of Washington, Seattle, WA, United States

Soil-transmitted helminths (STH) affect more than 1.45 billion people in low resource settings worldwide. The current WHO strategy of targeted deworming of preschool and school aged children is to control morbidity associated with STH. The DeWorm3 study is a series of cluster randomised trials being conducted in three countries (Benin, India and Malawi) to test the feasibility of interrupting STH transmission using bi-annual community-wide MDA compared to school-age targeted MDA. In India, the study is being carried out in 2 sub-sites, Timiri in Vellore district and Jawadhu Hills in Thiruvannamalai district of Tamil Nadu. A baseline census conducted from October to December, 2017, enumerated a total

of 37,246 households in Timiri (28,357) and Jawadhu Hills (8,889). The censused population (143,789) was fairly evenly distributed between males and females (p=0.996) and the age pyramid is similar to the country's age pyramid with the largest subgroup being young adults (15-39 years, 42.7%). Among the enumerated households, mud flooring was more common in JH (33%) compared to Timiri (6%). Household water supply also differed with 56.3% having piped drinking water in Timiri compared to only 2.6% in Jawadhu. High levels of open air defecation with no toilet in the household were documented in both study sites (Timiri, 56.8%) and (Jawadhu, 93.8%). A subset of 150 individuals from each cluster were recruited to a longitudinal monitoring cohort in age stratified sample (preschool age children, 30 PSAC 30, school age children, 30 SAC and 90 adults) accounting for a total of 6108. The prevalence of hookworm was higher in Jawadhu than Thimiri: 9.7%, 24.5%, 52.6% and 0.51%, 1.9%, 17.2% among PSAC, SAC and adults respectively. *Ascaris* and *Trichuris* infections were uncommon in both sites. In India, socioeconomic indicators, water and sanitation facilities are diverse, this coupled with significant variation in STH prevalence was evident in our study. Understanding these factors and cultural practices in endemic areas is essential to develop and implement appropriate community based strategies to interrupt STH transmission.

1961

HIGH PREVALENCE AND INTENSITY OF HOOKWORM IN AN INDIGENOUS COMMUNITY FROM PUERTO IGUAZU, MISIONES, ARGENTINA

Ernesto Candela-Senti[1], Carolina Goizueta[2], Marta Cabrera[3], Carla Muñoz-Antoli[1], **Maria V. Periago**[4]

[1]Departamento de Farmacia y Tecnología Farmacéutica y Parasitología, Facultad de Farmacia, Universidad de Valencia, Valencia, Spain, [2]Fundación Mundo Sano, Puerto Iguazú, Misiones, Argentina, [3]Instituto Nacional de Enfermedades Infecciosas, Administración Nacional de Laboratorios e Institutos de Salud "Dr. Carlos G. Malbrán", Buenos Aires, Argentina, [4]Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET), Fundación Mundo Sano, Buenos Aires, Argentina

Literature on soil-transmitted helminths (STHs) in Argentina covered 16 localities from only nine of the 25 Argentinian provinces. Previous studies from Misiones have detected varying prevalences of all four STHs (hookworm, *Strongyloides stercoralis*, *Ascaris lumbricoides* and *Trichuris trichiura)*, but none of these measured intensity of infection. The aim of this study was to determine the prevalence and intensity of STHs in an indigenous community from the city of Puerto Iguazú. The Fortín Mbororé community is composed of around 200 families of the Mbyá-Guaraní ethnicity and the primary source of income is from guided tours organized to visit the village, handcrafts and social plans. A total of 63 houses were visited, georeferenced and characterized through the use of a questionnaire. From the 240 containers distributed for the collection of stool samples, a total of 218 samples (90.8% participation) were received for coprological analysis. Age of participants ranged from 1 to 87 years old (mean = 20) and 53.2% of them were female. Stool samples were processed through sedimentation and Baermann techniques. Samples positive for STHs with any of the two techniques, except for those with mono-infections by *S. stercoralis*, were thoroughly processed with a Kato-Katz slide. The prevalence of STHs was 65.1%, being hookworm the most prevalent parasite (64.2%). Hookworm infections were either light (46.8%), most in a mean age of 23 years old, or heavy intensity (41.0%), most in a mean age of 20 years old. Other STHs found included *S. stercoralis* (n=22, 10.1%), *A. lumbricoides* (n=2, 0.9%) and *T. trichiura* (n=1, 0.5%). This study has detected a hyperendemic area for hookworm in Puerto Iguazú. Further studies will aim to study the association with environmental and socioeconomic variables as well as the effectiveness of mass drug administration in conjunction with preventive measures such as health education.

1962

EXPLORING SOCIOECONOMIC EQUITY IN THE REDUCTION OF HOOKWORM INFECTION PREVALENCE AND INTENSITY DURING THE TUMIKIA TRIAL

Emma Beaumont[1], Katherine Halliday[1], William Oswald[1], Elizabeth Allen[1], Stella Kepha[1], Stefan Witek-McManus[1], Charles Mwandawiro[2], Sammy Njenga[2], Carlos Mcharo[2], Paul M. Gichuki[2], Simon Brooker[1], Rachel Pullan[1]

[1]London School of Hygiene & Tropical Medicine, London, United Kingdom, [2]KEMRI (ESACIPAC), Nairobi, Kenya

The TUMIKIA project was a three-armed randomised controlled trial investigating the effectiveness and cost-effectiveness of alternative treatment strategies and delivery systems to interrupt transmission of soil-transmitted helminth infection in Kwale County, Kenya. The trial demonstrated that both prevalence and intensity of hookworm infection were reduced by expanding anthelmintic treatment with albendazole to all community members either annually or twice a year, in comparison to the current standard of providing children aged 2-14 with treatment once a year through schools. Both school- and community-based deworming are typically thought of as pro-poor interventions. Here we investigate socio-economic equity in the impact of these alternative control strategies. Defining SES in low and middle income settings is not straightforward, and current approaches based on asset indices may fail to adequately stratify individuals in very poor communities. We therefore explore the relative impact of the trial across alternative measures of SES, with a focus on those harbouring the heaviest infections. SES is a recognised risk factor for hookworm infection, and remains so throughout this trial with individuals from households of lower SES being at substantially greater risk of infection at baseline and after two years of treatment in all three arms. However, we did observe an equitable reduction in the prevalence of HK infection across the poorest, middle and least poor groups in all arms of the trial by the end of the study. SES also continued to be a risk factor for high intensity infections, however the poorest groups appear to have experienced a greater reduction in the risk of high intensity infection in comparison to the middle and least poor groups. Understanding the impact of intervention strategies in these high risk groups can help programmes to improve vertical equity by tailoring interventions to reach the most vulnerable.

1963

THE IMPACT OF DATA UNCERTAINTY ON MODEL PREDICTIONS FOR SOIL-TRANSMITTED HELMINTHS

Marleen Werkman, Roy M. Anderson

Imperial College London, London, United Kingdom

Anthelminthic therapy is effective against *Ascaris* and hookworm. And the World Health Organisation (WHO) recommends treating 75% of all SAC by mass drug administration (MDA) to reduce STH induced morbidity. However, this target is not always achievable due to a variety of reasons including school absence or limited access to remote areas. Mathematical models can assist in optimising the treatment strategy to achieve the WHO morbidity goals. We have developed a parasite transmission model that includes density-dependent fecundity, age-intensity profiles and aggregation of worm burden. The data needed to fit the model parameters are scarce and its quality varies widely across different settings. An example of this is the MDA coverage, which is often difficult to estimate as the underlying demography is unknown. In this study, we investigate the impact of the uncertainty of MDA coverage data. The model is fitted to baseline prevalence data (assuming no historic treatment) and endline prevalence data (data collected after a MDA program). We fit all model parameters using Gibbs-sampling MCMC techniques and assume different achieved coverage levels for the MDA program. Additionally, we make forward projections with the fitted models to investigate the impact of data uncertainty on model predictions. Our

results illustrate that uncertainty of MDA coverage data plays a crucial role in determining the efficacy of MDA programs and highlight the need of high quality coverage data.

1964

QPCR DIAGNOSTICS FOR *ASCARIS LUMBRICOIDES*: CHARACTERIZING THE CONNECTION BETWEEN QPCR, KATO KATZ AND WORM BURDEN

James Truscott[1], Alice Easton[2]

[1]Imperial College London, London, United Kingdom, [2]National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD, United States

For a number of helminth parasites, new diagnostic techniques have been developed and are now starting to be used in the field. Traditional techniques involving egg counts are being superseded by antigen-based (e.g. CCA for schistosomes) approaches and PCR methods. To achieve continuity as diagnostics change, it is important to understand the relationship between the different diagnostic results. For example, the WHO treatment guidelines for control are in terms of prevalence as measured by egg-counting techniques and community-level morbidity assessments are often based on intensity thresholds from the same techniques. How will these guidelines be affected by new diagnostics? The data used in this analysis is from a study carried out in western Kenya, comprising a baseline infection survey and a follow-up survey several months after mass drug administration. We analyse *Ascaris lumbricoides* infection data from both time points, consisting of matching Kato-Katz, qPCR and expulsion data. We construct a model of host infection and diagnosis that is, as far as possible, based on realistic biological mechanisms. Bayesian methods are employed to fit our model to the data, employing prior estimates of key parameter values. Our underlying mechanistic model allows us to characterise the distribution of both egg counts and qPCR output as a function of the underlying worm burden of the host. It is then possible to construct the statistical relationship between qPCR readings and Kato-Katz egg counts, allowing an approximate conversion between qPCR output and standard thresholds of light, medium and heavy infection at the individual level. Applying these results at the population level, we show the implications for the sensitivity of the Kato-Katz diagnostic technique over a wide range of prevalences. Results for very low prevalences are particularly important in light of the increasing interest in elimination of soil transmitted helminths.

1965

PREVALENCE OF STRONGYLOIDIASIS IN SOLID ORGAN TRANSPLANT PATIENTS AND POST-TREATMENT TEST-OF-CURE EFFICACY

Haley Pritchard, Vagish Hemmige, Alejandro Restrepo, Rojelio Mejia

Baylor College of Medicine, Houston, TX, United States

Immunosuppression of a host with chronic *Strongyloides stercoralis* infection can lead to hyperinfection syndrome or dissemination. Screening for *S. stercoralis* in transplant patients is done with commercial crude-antigen enzyme-linked immunoassays (ELISAs) known to cross-react with other helminths. NIE is a specific recombinant *S. stercoralis*-specific antigen. We used *S. stercoralis*-specific NIE Ss IgG ELISA to assess the prevalence of strongyloidiasis in transplant patients. We prospectively recruited 150 solid organ transplant patients from endemic regions. Serum was sent for commercial *Strongyloides* IgG ELISA and a recombinant NIE Ss IgG ELISA was performed on all serum samples at our institution. Metadata including demographics, transplant status, absolute eosinophil count, and immunosuppressive regimen were recorded. Preliminary data yielded a median age of 64 years old with 76% of patients were from Latin America, 12% from the Middle East, 7% from Asia, and 4% from Africa, and 1% from Eastern Europe. Commercial *Strongyloides* ELISA yielded 10.7% positives and NIE Ss IgG ELISA was positive in 5.9% of all patients (80% pre-transplant, 20% post-transplant). There was a significant increase in *S. stercoralis* IgG using the NIE Ss ELISA compared to commercial assays (geometric mean 18.3 vs 9.84, p=0.0001). Eosinophilia was higher for patients with positive NIE Ss ELISA or commercial ELISA versus negative assays (geometric mean 560, 383, and 122 cells/µl respectively, p=0.0096). NIE Ss IgG ELISA had a specificity of 97% and a 92% negative predictive value (p=0.001) for *S. stercoralis* infection in this population. We found an endemic prevalence of strongyloidiasis at our institution in the solid organ transplant population. The NIE Ss IgG ELISA is specific for *S. stercoralis*. Eosinophil degranulation proteins will be assayed and associated with activated eosinophils in transplant patients with strongyloidiasis. Post-treatment efficacy will be completed prior to conference. We recommend screening all at-risk solid organ transplant patients for strongyloidiasis, especially those with eosinophilia.

1966

PREVALENCE OF STRONGYLOIDIASIS IN GUATEMALA INCLUDING AN AT-RISK IMMUNOSUPPRESSED POPULATION

Paul Arkell[1], Miriam Canet[2], Iris Cazali[3], Philip Cooper[1], Rojelio Mejia[4]

[1]St. George's, University of London., London, United Kingdom, [2]Hospital Roosevelt, Guatemala City, Guatemala, [3]Hospital Roosvelt, Guatemela City, Guatemala, [4]Baylor College of Medicine, Houston, TX, United States

Strongyloidiasis is a neglected tropical disease likely underestimated to affect 100 million people worldwide. While the majority of disease burden relates to a chronic insidious effect on health, loss of immune control can lead to potentially fatal hyperinfection syndrome, a condition particularly associated with corticosteroid treatment. The aim of this study was to investigate seroprevalence of *Strongyloides stercoralis* in two populations in Guatemala, including a group of individuals potentially at risk of hyperinfection syndrome. In phase I, serum was collected from consecutive patients presenting with fever symptoms to a health centre in a rural area. In phase II, existing serum samples from patients seen in a rheumatology clinic in Guatemala City were randomly selected from computerized clinic records. Serum samples were analyzed for antibodies to *Strongyloides stercoralis using* a recombinant antigen NIE-ELISA assay, which has been validated to be more sensitive and specific for strongyloidiasis than other somatic antigen assays. The NIE-ELISA has no cross-reactivity to other helminths, which are endemic in Guatemala. In phase I, 49 out of 446 individuals were positive (seroprevalence in rural cohort = 11%). There was no significant association between antibody titre and age or gender. In phase II, 7 out of 106 individuals were positive (seroprevalence in urban-immunosuppressed cohort = 6.5%). We report high *Strongyloides stercoralis* prevalence in Guatemala, including in rheumatology patients who are taking immunosuppressive steroids and at increased risk of hyperinfection syndrome. Further work looking at risk-factors, infection intensity, and treatment response is needed to inform optimal testing and treatment strategies for *Strongyloides stercoralis* in this group of patients.

1967

DETECTING THE PREVALENCE OF CHAGAS DISEASE AMONG PEOPLE LIVING WITH HIV/AIDS IN LOS ANGELES COUNTY, CALIFORNIA

Tyler B. Evans[1], Quoc Phung T. Than[2], Leonardo Colemon[1], Adam C. Sukhija-Cohen[1], Otto O. Yang[3]

[1]AIDS Healthcare Foundation, Los Angeles, CA, United States, [2]California State University Northridge, Northridge, CA, United States, [3]University of California Los Angeles, Los Angeles, CA, United States

Chagas disease (CD) is a well-known tropical parasitic disease with a historical footprint in Latin America. Unfortunately, a qualified detection system to identify CD is largely missing in the global north, with over 300,000 estimated cases in the United States alone (Meymandi et al. 2017). In a recent analysis of foreign-born Latin American patients being screened in Los Angeles County (LAC), CD was detected in 1.24%

of the population (Meymandi et al. 2017). CD is known to follow an insidious course, leading to a number of chronic outcomes, including cardiomyopathy. Special populations, including people living with HIV and AIDS (PLWHA) may be at a higher risk of CD and its progression to adverse outcomes. This hypothesized risk calls for a large sample size to explore the risk of CD among PLWHA in the United States. The objective of this study is to (1) measure the prevalence of CD among Latin American foreign-born PLWHA residing in LAC, CA and (2) investigate the associated with CD. Retrospective data analysis of Latin American foreign-born PLWHA aged 18 and above years seeking services at AIDS Healthcare Foundation (AHF) Healthcare Centers (HCCs) between 05/01/2017 and 03/31/2018. Descriptive analyses were performed using frequency distributions and nonparametric chi-square tests to examine the prevalence of CD. Two clients out of a subpopulation of 179 were identified as CD-positive ($p < 0.01$): one male and one female, both originating from Honduras. The prevalence documented at AHF Healthcare Centers (1.11%) is slightly lower than the 1.24% prevalence reported previously in LA County (1.24%) reported by Meymandi et al. (2017). While this is a relatively small sample size, the statistically significant results suggest developing CD testing and treatment guidelines among Latin American foreign-born PLHWA—a prominent subpopulation in LAC.

1968

ASSOCIATION OF FUNCTIONAL GENOTYPES AND HAPLOTYPES IN ADIPONECTIN GENE WITH BMI, VIRAL LOAD AND CD4⁺ T CELL COUNT AMONG HIV-1 INFECTED ANTIRETROVIRAL TREATMENT NAÏVE AND EXPERIENCED KENYAN INJECTION SUBSTANCE USERS

Nathan Shaviya

Masinde Muliro University of Science and Technology, Kakamega, Kenya

Human immunodeficiency virus (HIV) and injection drug use have both direct effect on and epigenetic effects on genes. These effects could be beneficial or detrimental in defining disease outcomes. *ADIPOQ* gene is key in modulating metabolic and immunoregulatory functions. Understanding the effects of HIV and injection drug use on the gene in the context of antiretroviral therapy is important for predicting disease outcomes. This cross-sectional genetic study determined polymorphisms in the promoter region of the *ADIPOQ* gene. Two loci of *ADIPOQ* gene were analyzed rs2241766 and rs266729.The polymorphisms were associated with clinical markers of disease outcome; BMI, viral load and CD4+ T cell count. The selected SNPs were amplified via PCR then genotyped via random fragment length polymorphism. The GG genotype at locus rs266729 was associated with low BMI (OR = 2.03; 95% CI; 1.11-3.70; P = 0.021). GC haplotype was associated with low CD4+ T cell count (OR = 1.91; 95% CI; 1.54-3.51; P = 0.036), while GG haplotype was associated with a high viral load (OR = 2.14; 95% CI; 1.27-4.26; P = 0.011). TC haplotype was associated with a high BMI (OR = 1.79; 95% CI; 1.86-3.16; P = 0.042) and TG haplotype was also associated with a high BMI (OR = 1.97; 95% CI; 1.12-3.48; P = 0.019). The study revealed functional genotypes and haplotypes of the *ADIPOQ* gene at loci rs2241766 and rs266729 that could determine disease outcomes in HIV-1 antiretroviral therapy naïve and experienced injection drug users.

1969

FACTORS ASSOCIATED WITH PMTCT UTILIZATION AMONG HIV-INFECTED WOMEN

Mutinta Hamahuwa[1], Yvonnie Phiri[1], Pauline Manyepa[1], Nkumbula Moyo[1], Jane Mutanga[1], Phil E. Thuma[1], William J. Moss[2], Catherine G. Sutcliffe[2]

[1]Macha Research Trust, Choma, Zambia, [2]Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States

Prevention of mother-to-child transmission (PMTCT) has led to significant decreases in the number of infants acquiring HIV infection. For barriers to be addressed and PMTCT programs to reach their target, a better understanding of women not being reached and at high risk of transmitting HIV to their infants is needed in the era of option B+ and in diverse settings. A prospective study was conducted of HIV-infected pregnant women delivering their infants at seven health facilities in Southern Province, Zambia from February 1, 2016 to January 31, 2018. The health facilities included Macha, Livingstone Central Hospitals and associated health centers. Mothers were administered a questionnaire, a chart review was completed and a dried blood sample was collected from the infant and sent to the central laboratory for HIV DNA testing. Of the 802 mother-infant pairs enrolled in the study, 794 had complete data and were included in the analysis. 92% of mothers received PMTCT. Infants born to mothers who did not receive PMTCT were more likely to have detectable HIV DNA at birth (3.0% vs. 1.0%; p = 0.17). Mothers who did not receive PMTCT were younger (28 vs. 30 years; p= 0.06), less likely to have received antenatal care (3.0% vs. 0.7%; p = 0.05), and more likely to report having been diagnosed with HIV infection during pregnancy (62.5% vs. 32.8%) or during labour (7.1% vs. 0.1%; p<0.0001). Among all mothers, 84.9% reported having been tested and knowing their status before the pregnancy. Among mothers diagnosed with HIV during pregnancy (n=275), 60.4% reported having been tested prior to the pregnancy. Among mothers diagnosed with HIV during labour (n=5), 80.0% and 20.0% reported having been tested prior to and during the pregnancy, respectively. PMTCT programs were effective in identifying and treating HIV-infected pregnant women. Few women eligible for PMTCT were missed as most women who did not receive PMTCT were diagnosed during pregnancy or labour. Frequent HIV testing of women should be emphasized to facilitate early diagnosis and treatment and prevent HIV transmission to their infants.

1970

THE USE OF DIGITAL DATA CAPTURE SYSTEMS IN EVALUATING THE IMPACT OF COMMUNITY HEALTH WORKERS INTERVENTION ON ANTIRETROVIRAL THERAPY RETENTION AND ADHERENCE IN TANZANIA

Neema S. Gamasa

Ifakara Health Institute, Dar es Salaam, United Republic of Tanzania

The introduction of numerous HIV/AIDS prevention projects and campaigns by the Ministry of Health and donor parties have made significant gains in the scale-up of antiretroviral (ART) usage, thus the number of people on ART has been increasing since 2010. However, the adherence of infected people in attending comprehensive treatment centre (CTC) clinics on a monthly basis has not been consistent due to factors such as stigma, seasoned agriculture activities and lack of money for transport given that some people live far from their CTC clinics. Our study is evaluating ART program retention and viral load measures from clients receiving the existing standard of care CTC clinics, compared to clients receiving community health worker support for delivering ART medicines to HIV infected people in their communities. Multiple digital applications, including community mobile data collection via the online data kit (ODK), an online data portal, and a routine data archiving system have been implemented for this study to make sure all required data are well-captured. To better understand the adherence of participants in both study arms the study setup 20 sites (10 control and 10 intervention) in three regions of Tanzania. A total of 1986 participants were interviewed in the baseline phase, from whom tablet-based ODK forms were used to capture survey information, CTC record, and viral load data. Currently the study is collecting 12-month data, where behavioral surveys, clinic records, and viral load measures are again captured for comparison with the baseline data. The online portal was designed to provide summary information on the collected data which project managers and the data collectors can access the system at any time. As the study continues, the use of these multiple digital applications has proven to be highly effective in providing accurate data, secured data and reduced time lag between data collection, analysis and sharing with the partners.

1971

COÏNFECTIONS *OF SCHISTOSOMA HAEMATOBIUM* AMONGST HIV-SEROPOSITIVE AND -SERONEGATIVE WOMEN: KISANTU HEALTH ZONE, DEMOCRATIC REPUBLIC OF CONGO

Gisele M. Mvumbi[1], Adva Gadoth[2], Nicole A. Hoff[2], Kamy Musene[1], Patrick Mukadi[3], Rachel A. Martin-Blais[4], Emile Okitolonda-Wemakoy[1], Jean-Jacques Muyembe[3], Anne Rimoin[2]

[1]Kinshasa School of Public Health, Kinshasa, Democratic Republic of the Congo, [2]Fielding School of Public Health, University of California Los Angeles, Los Angeles, CA, United States, [3]Institut National de Recherche Biomédicale, Kinshasa, Democratic Republic of the Congo, [4]Department of Pediatrics, University of California Los Angeles, Los Angeles, CA, United States

Schistosoma haematobium (SH) infection is a significant cause of morbidity amongst females in endemic regions, causing development of urogenital lesions which leave women vulnerable to the acquisition of HIV. However, HIV-SH co-infection has been poorly characterized in endemic zones, despite the fact that the parasite poses a serious health concern. In Kisantu, the reported prevalence of *S.mansoni* is 61.8%, yet *S.haematobium* is not monitored, making the scope of the problem (and its potential consequences) in this population difficult to ascertain. We conducted a cross-sectional analysis between October 2016 and February 2017 in the Kisantu Health Zone, DRC, to compare rates of *Schistosoma haematobium* infections between HIV-seropositive and -seronegative women. Interviews based on standardized questionnaires were administered to 383 consenting women who tested negative and 63 women who tested positive for HIV; afterward, urine and blood samples were collected and analyzed. *Schistosoma* infection was confirmed via urine microscopy and HIV infection was confirmed using rapid tests listed in DRC's 2017 National Algorithm for HIV Diagnosis (Determine™, Uni-Gold™, and Double Check™). The overall prevalence of SH among all study participants was 18.2% (95% CI: 15.0-22.2). The rate of SH co-infection amongst women positive for HIV was 37.3% (95% CI: 32.8%, 41.8%), while only 15.2% of women negative for HIV were found to harbor SH infection (95% CI: 11.9%, 18.5%). This study demonstrates significantly higher prevalence of SH infection in HIV-positive women than in HIV-negative women and emphasizes the importance of continued SH testing and communal treatment schistosomiasis-endemic regions, especially among vulnerable populations.

1972

IMPROVING CONTINUUM OF CARE IN DOMINICAN REPUBLIC FOR HIV-INFECTED PATIENTS CO-INFECTED WITH HEPATITIS B AND C

Leandro Tapia[1], Paola Peña[1], Laura Manosalvas[1], Angiolina Camilo[2], Jean-Pierre Routy[3], Robert Paulino-Ramirez[1]

[1]Institute for Tropical Medicine & Global Health, Universidad Iberoamericana, Santo Domingo, Dominican Republic, [2]School of Medicine, Universidad Iberoamericana, Santo Domingo, Dominican Republic, [3]Division of Hematology and Chronic Viral Illness, McGill University Health Center, Montreal, QC, Canada

The estimated prevalence of hepatitis B and C among people living with HIV/AIDS is 5–20% and 6% respectively in Latin America, representing 2 to 4 million people[1]. Liver diseases has become in the ART era the major cause of morbidity and mortality among PLWHIV[2]. The effective management of HIV people co-infected with hepatitis B and C is a public heath priority requiring testing service, linkage to care and access to treatment[3]. The objective of this study was to evaluate indicators involved with optimal cascade of care for HBV and HCV co-infected PLWHIV in Dominican Republic. Patients enrolled in care in two community-based clinics in Santo Domingo and Santiago, DR were evaluated for clinical indicators of HBV, HCV and HIV infections. Socio-demographic determinants and serological/chemical data were collected from clinical files, and statistical analyses were used to assess their distribution in different key populations like MSM, Trans, and drug users. A total of 2787 HIV-infected patients were evaluated. Co-infection with HBV was found in 28 patients, and 100% were followed up, 85.7% (n=24) of them were retained in care and ARV containing tenofovir were prescribed to 71.4% (n=20). HCV co-infection was identified in 8 patients, and 87.5% (n=7) were followed, while 75%% (n=6) were retained to care without receiving treatment for HCV. This study identified significant differences between the continuum of care of HBV and HCV co-infections. Access to HCV treatment in co-infected populations is crucial for care and in turn to decrease new infections. However, seems to be a subregistry on hepatitis status compared with the current epidemiological data from the region. A more systematic screening for viral hepatitis among PLWHIV will be essential for early management and treatment. Increased detection, linkage to care and long-term follow up with access to medication and HBV vaccination are public health priority to improve patient outcome and curb these epidemics.

1973

IMPROVING THE MONITORING OF TUBERCULOSIS INFECTIONS IN PEOPLE LIVING WITH HIV IN THE DOMINICAN REPUBLIC: A CASCAADE OF CARE MODEL

Jaimee Esperanza King, Angela Baez, Leandro Tapia, Robert Paulino-Ramirez

Institute for Tropical Medicine & Global Health, Universidad Iberoamericana, Santo Domingo, Dominican Republic

Among the opportunistic infections in people living with HIV (PLWHIV), infections with M. tuberculosis appear to be the most common detected. To the date it is estimated a total of 268,500 patients per year in Latinamerica, and the Dominican Republic it estimated 59.8 cases per 100,000 in the general population, and 12% of co-infection TB/HIV has been reported by 2016[1,2]. This study is aim to propose a cascade of care for the TB/HIV for monitoring of interventions.We collected epidemiological data from three HIV primary care units from the two larger provinces in DR: Santo Domingo, and Santiago. Criteria for a positive TB infection were obtained from clinical records, based on clinical manifestations, and (+) baciloscopy/X-rays. Also, the criterion for a TB infection was not limited to pulmonary, but also included extrapulmonary infections (ganglionar, renal, etc). We analysed data by key populations (MSM/TG, Female Sexual Workers (FSWs), Drug uses (DU), and Migrants. A total of 5537 HIV (+) patients were enrolled in these three centres. Of those, 1% was confirmed as TB (+) (n=71). Among those TB/HIV (+) 41% received treatment, and 11% was considered cured (Figure 1). Among key populations, treatment access was higher (40% GP vs 46% KPs), however, cure rate was lower among KPs (8%) compared with GP (13%). Within those KPs: FSWs and MSM/TG were lower compared with migrants and DU (0% and 9%, respectively). This study revealed a disparity on access to care for tuberculosis treatment between general population and key populations; early access to care, and specific barriers of retention and early management might influence this. When compared between each KP, the lower rate of cure was observed in FSWs and MSM/TG, these findings are consistent with other studies from the DR where we also observed lower rates of retention in care and not achieving the final goal of finalizing TB treatment. Seems to be a subregistry of TB/HIV cases based on current epidemiological data from the region. This propose model of cascade of care is based on data reported and It is necessary a more intensive screening and retention to achieve the goal of a free TB-generation by 2020.

1974

A RARE CAUSE OF OLECRANON BURSITIS IN AN IMMUNOCOMPROMISED PATIENT: *PROTOTHECA WICKERHAMII*

Kruti Yagnik, Raphaël Bossé, Rachel Butts, Jennifer Reppucci, Shehla Islam, Anthony Cannella

University of Florida, Gainesville, FL, United States

Human protothecosis is a rare algal infection caused by *Prototheca* spp; it is a ubiquitous achlorophyllic algae, and is the only known algae to cause human disease. Currently, the pathogenesis remains unclear and no treatment options have been adequately studied. Here, we present a case of olecranon bursitis caused by *Prototheca wickerhamii* in an immunocompromised patient. Six months prior to his presentation to our institution, a 45-year-old presented with left elbow pain after reportedly scraping his left elbow on a tree while doing yard work. He reported significant pain and swelling of the elbow after injury, which resolved on its own without intervention. He was diagnosed with HIV at that time and subsequently started on antiretrovirals. A short while later, he experienced recurrent elbow swelling and pain; an incision and drainage was performed and cultures demonstrated *P. wickerhamii*. He was unsuccessfully treated with oral voriconazole, and an attempt at treatment with IV amphotericin and oral doxycycline was made. However, he left against medical advice and presented to our institution. At presentation, both IV amphotericin and doxycycline were instituted with planned outpatient bursectomy. He clinically improved on that regimen but left against medical advice again prior to completing his anti-infective agent course. A six-week course of IV amphotericin and oral doxycycline was slated for recommendation for the *Protothec*a infection. Given the rarity of this pathogen, no official treatment guidelines exist and there are few studies analyzing the susceptibility of *Prototheca* to medication. Treatment is challenging due to slow-growing nature of the algae, the paucity of research studies, and the limited susceptibility of this pathogen. Furthermore, patients diagnosed with disseminated *P. wickerhamii* can have a mortality rate upwards of 67%. This case adds to the limited body of literature on this global organism by demonstrating the clinical presentation of protothecosis and highlighting the pathology and current treatment options.

1975

CRACK LUNG MIMICKING MILIARY TUBERCULOSIS AND FUNGAL DISEASES IN A HIV-INFECTED PATIENT

Andréa B. Doltrário, Lude B. Silveira, Rafael F. Silva, Fernando C. Vilar, Anna Christina T. Silva, Mariana C. Salomão, Rivian C. Faiolla, Joel Del Pádua, **Benedito A. Fonseca**, Roberto Martinez

School of Medicine of Ribeirão Preto, Ribeirão Preto, S.P., Brazil

A 45-year-old female, HIV-infected patient, with a history of abusive use of inhaled cocaine, crack and marijuana was admitted to our service presenting with weight loss, fever, dyspnea, productive cough, sometimes with hemoptysis, during the last year. Her symptoms had worsened in the last few days before admission evolving to a severe dyspnea. At admission, the patient presented with oxygen saturation level of 85% at room air, diffuse wheezing and fine rales, and a respiratory rate of 26 breaths per minute. Chest x-ray showed a diffuse miliary infiltrate and a cavitated lung lesion at left lung. Due to a low CD4+ cell count, fluconazole for oral candidiasis and treatment for miliary tuberculosis and *Pneumocystis jiroveci* pneumonia were initiated. Sputum and gastric fluid smears for *Mycobacterium tuberculosis* were negative. Xpert MTB/RIF evaluation of the same samples was also negative. A higher dose of fluconazole was prescribed after a detection of a titer of 1:16 to *Paracoccidioides brasiliensis* and biopsy of a skin lesion showing the presence of fungi suggestive of *Cryptococcus neoformans*. Bronchoscopic examination showed a diffuse airway inflammation and histopathological evaluation of pulmonary biopsies revealed foreign body filamentary structures resembling suture material, lymphoplasmocitary infiltrates, exuberating peribronchial anthracotic pigmentation suggesting a ulcerated lymphocytic bronchitis. All laboratory investigations were negative for the presence of pathogens in the bronchoalveolar lavage. No granulomas were observed and staining for fungi, mycobacteria or other bacteria was also negative. Considering the diagnosis of crack lung, tuberculosis treatment was discontinued but treatment for either Paracoccidioidomycosis or Cryptococcosis with fluconazole remained. The patient experienced a great clinical improvement and further cultures (sputum, gastric fluid, bronchoalveolar lavage and skin biopsies) remained negatives for mycobacteria and fungi reinforcing the diagnosis of crack lung presenting with pulmonary features of either miliary tuberculosis or Paracoccidioidomycosis.

1976

SUCCESSFUL TREATMENT OF DISSEMINATED STRONGYLOIDIASIS WITH SUBCUTANEOUS IVERMECTIN

Lude B. Silveira, Andréa B. Doltrário, Rafael F. Silva, Fernando C. Vilar, Anna Christine T. Silva, Mariana C. Salomão, Rivian C. Faiolla, Alexandre T. Fabro, **Benedito A. Fonseca**, Roberto Martinez

School of Medicine of Ribeirão Preto, Ribeirão Preto, S.P., Brazil

A 35-year-old male, HIV-infected patient was admitted to our hospital complaining of a watery diarrhea of about 10 episodes a day, initiated four months from admission. Ambulatory treatment with Co-trimoxazole had been initiated at the beginning of the disease, but as there was no improvement of the symptoms it was suspended. Four days before admission, the patient started with nausea and incoercible vomiting accompanied by tachypnea and fever. On clinical examination, he was pale and with fine rales at lung bases. As CD4+ count was 22 cells/mm^3, empirical treatment for *Pneumocystis jiroveci* pneumonia was prescribed. After two days, he needed orotracheal intubation with further improvement of respiratory symptoms within the next 9 days. He then developed gastrointestinal bleeding and an endoscopic examination showed ulcerated lesions at gastro-esophageal junction without signs of active bleeding. The duodenal mucosa was friable and with multiple bleeding spots. Parasitological evaluation showed *Ancylostoma* sp eggs and *Strongyloides stercoralis* larvae. Other common causes of diarrhea were excluded. Gastric mucosa biopsies revealed countless helminthes on lumen of mucosal glands suggestive of *Strongyloides stercoralis*. Oral treatment with albendazol was initiated but soon switched to ivermectin by the rectal route because the patient had copious gastric daily drainage of more than 1,500 mL of gastric content. Oral ivermectin was prescribed after gastric drainage diminished, but after 10 days of treatment the parasitological analysis of the gastric fluid remained positive for *Strongyloides stercoralis* larvae. Subcutaneous veterinary-grade ivermectin was prescribed for 7 days. Parasitological analyses of feces and gastric fluid were negative the day after the end of treatment. Gastrointestinal bleeding ceased and the patient condition improved without need for repeating the treatment. This case report underscores the importance of disseminated *Strongyloides stercoralis* infection in immunosuppressed patients and that, sometimes, drastic approaches, such as using veterinary drugs, are needed for a successful treatment.

1977

ANTIBIOTIC RESISTANCE IN CHRONIC SUPPURATIVE OTITIS MEDIA IN A HIGH PREVALENCE HIV SETTING IN SWAZILAND: TIME FOR CHANGE

Bongani Chirigo, **Jessica A. Kumar**

Baylor International Pediatric AIDS Initiative Baylor College of Medicine, Mbabane, Swaziland

Many HIV-infected patients in Swaziland have perforated tympanic membranes and deafness from recurrent or unresolved ear infections despite having completed multiple short courses of the same ineffective antibiotic based on country guidelines. Chronic infections cause severe

disability and morbidity in resource poor countries. In Swaziland, there is no consistent medical record keeping or continuity of care. Patients do not have ready access to specialty services and there are limitations in available antibiotics. School performance is compromised and there are no regular hearing screening or services for the deaf in country. We conducted a quality improvement project to understand the antimicrobial susceptibility patterns in chronic, recurrent ear infections among HIV+ patients who seek care at the Baylor College of Medicine's pediatric AIDS clinics. Patients were selected based on complaints of ear drainage, re-occurring otitis media and hearing loss. Ear drainage samples from 24 HIV patients who had received at least one course of treatment per Swaziland guidelines without prior cultures ages 2-24 yrs (mean 12 yrs) with a range of CD4 counts 257-1766 cells/uL (mean 870) were collected and sent for culture and sensitivity. Preliminary results from April-May 2017 show primarily gram negative bacterial pathogens like *Proteus* and *Pseudomonas. Proteus* had variable sensitivity but *Pseudomonas* remained sensitive to most anti-pseudomonal agents. Two *Staphylococcus aureus* isolates were resistant to penicillin and sulfamethoxazole-trimethoprim. There was resistance to third and fourth generation cephalosporins and even meropenem. As expected, resistance rates reflected the preferred antibiotics listed in the country guidelines for regimens to treat otitis media. Treatment particularly in refractory cases should be guided by antibiotic susceptibility testing. This data can contribute to the development of an antibiogram informing medication supply purchasing, availability as well as treatment guidelines in this immunocompromised population not addressed in current guidelines.

1978

CARBON NANOTUBE AS A NOVEL HIV-1 VACCINE ANTIGEN VECTOR FOR MUCOSAL IMMUNITY STIMULATION

Yang Xu[1], Brad Brooks[1], Ziyou Zhou[1], Tammy Ferguson[1], Xiangpeng Kong[2]

[1]Luna Innovations Inc, Danville, VA, United States, [2]New York University School of Medicine, New York, NY, United States

Developing a safe and effective preventive HIV-1 vaccine remains the hope for controlling the global AIDS epidemic. A mucosal vaccine offers several advantages including non-invasive application, elicitation of both systemic and mucosal immune responses. Currently, the problem with the use of proteins in HIV vaccines is that they are generally far less immunogenic than live or killed whole organism vaccines. Therefore there are major needs for a new HIV antigen delivery platform to enhance these immunogenicity of proteins. Luna has developed a needle free carbon nanotube HIV-1 vaccine (CNTVac) delivery platform that is capable of delivering antigens mucosally to prevent HIV-1 infections. The needle-shape CNTs demonstrated faster entry into antigen-presenting cells (APCs) compared with other spherical nanoparticles, which significantly increased the utility of antigens and shorten the time to effect. CNTVac was bio-mimetic to the dimension of HIV particle (length and diameter). The modified gp120 surface protein coating density on CNTs was fully characterized to mimic HIV. Luna's CNTVac has experimentally demonstrated to be easily recognized and taken up by APCs for induction of much greater (10 times) immune responses compared to protein alone. Luna's biocompatible nasal vaccine formulation has also exhibit increased epithelial permeability (~ 6 times higher than control) using a surrogate marker TEER and flux assay for measuring the integrity of intracellular junction dynamics. CNTVac has multiple copies of antigens (same or different) without changing their immunogenicity and enables the intracellular multiple antigens uptake, which reduces the ratio of the delivery vehicle and maximizes the effective dose of antigens and the delivery efficiency.

1979

IMPLEMENTATION OF AN EXTERNAL QUALITY CONTROL PROGRAM FOR HIV RAPID TEST IN THE PERUVIAN ARMED FORCES

Diana Vega[1], Rose M. Sagastegui[2], Fernando Ruiz[2], Alejandro Mercado[2], Carley Simpson[3], Mark. P Simons[4], Jorge Alarcon[5], Silvia M. Montano[4]

[1]U.S. Naval Medical Research Unit No. 6 (NAMRU-6) and Asociacion Benefica PRISMA, Lima, Peru, [2]Peruvian Armed Forces and Police Committee for the Prevention of HIV/AIDS (COPRECOS), Lima, Peru, [3]DoD HIV/AIDS Prevention Program (DHAPP), San Diego, CA, United States, [4]U.S. Naval Medical Research Unit No. 6 (NAMRU-6), Lima, Peru, [5]Universidad Nacional Mayor de San Marcos, Lima, Peru

While HIV rapid test and WHO-approved diagnosis algorithms have greatly improved the field diagnosis and linkage to care, External Quality Control (EQC) of HIV rapid test is critical to monitor and improve the quality of testing. Unfortunately, the EQC programs are expensive and often lacking in resource-limited settings. Proficiency testing (PT) using dried tube specimen (DTS) is a simple, low-cost and practical method developed by the Centers for Disease Control and Prevention (CDC) to prepare and distribute PT panels and implement an EQC program attainable in a wider variety of HIV testing settings. The aim of our effort with COPRECOS, NAMRU-6, DHAPP and UNMSM was to improve the quality of HIV rapid testing processes in military health facilities in Peru through an EQC program using the DTS method. Two PT training workshops using DTS were conducted for 29 health workers who perform HIV rapid test. These were followed by the implementation of an EQC program for HIV rapid test using DTS in 10 military health facilities in 2016 and then 18 in 2017. Three PT panels were sent to participating sites, 10 in Lima and 08 in other provinces every 3-4 months during both years. Test results were collected and entered into a customized Microsoft Excel spreadsheet. PT performance was evaluated according to the panel and documentation scores, and appropriate corrective actions were taken following the CDC decision tree. Among the health facilities assessed, the baseline average PT performance was 75% in 2016 and 94% in 2017. The main reasons for unsatisfactory results in the 2016 PT were the misinterpretation of final results and incomplete final report. The assessments also showed that the national HIV testing algorithm was not followed. In 2017, only minor errors were observed during the PT. At the end of the 6 PT assessments, both the 2016 and 2017 testing groups scored 100%. Implementing an EQC program dramatically improved performance for HIV rapid test process and the accuracy of results across facilities. Extension of the program to include other military health units performing HIV testing and planning for long-term sustainability are ongoing.

1980

CHAGAS DISEASE. A SYSTEMATIC REVIEW OF CASE REPORTS THROUGH THE XXI CENTURY

Diego Abelardo Álvarez Hernández[1], María José Díaz Huízar[2], Alberto Manuel González Chávez[2], Rodolfo García Díaz Arana[3], Jorge Alberto Ascencio Aragón[3], Yolanda Hernández Ponce[3], Mariana Álvarez Sánchez[3], Emmanuel Estefan Melgarejo[3], Rosalino Vázquez López[3], Ana María Fernández Presas[4]

[1]Fundación Carlos Slim, Mexico City, Mexico, [2]Hospital Español de México, Mexico City, Mexico, [3]Universidad Anáhuac México Campus Norte, Mexico State, Mexico, [4]Universidad Nacional Autónoma de México, Mexico City, Mexico

Chagas disease is a parasitic disease caused by *Trypanosoma cruzi*, a protozoan which is transmitted to humans primarily vector-borne. During its early stage patients may remain asymptomatic or may present unspecific manifestations, meanwhile during the late stage they may develop life-threatening complications. It frequently goes underdiagnosed and therefore remains untreated. The objective of our review was to describe the epidemiology of published cases to aid with

the characterization of the disease. A systematic review was conducted following the "*PRISMA*" guideline. PubMed database was searched using the search terms "*Chagas disease*" or "*American trypanosomiasis*" and limited to case reports published in English or Spanish, but without time frame. Full text articles were assessed for relevance and data extraction was performed as an iterative process. During the initial search 250 articles were obtained, from which 136, containing 205 cases were included. Males were more affected than females (111 vs 94) and the medium age of presentation was 35.78 years (+/-SD 19.47). Non-vector-borne transmission was reported in 32% of the cases and vector-borne in only 7%. The route of transmission remained unknown in 61% of the cases. Fever (39%), headache (13%) and malaise (11%) were the most common initial clinical manifestations, meanwhile dyspnea (25%), chest pain (22%) and edema (21%) were the most common late ones. Cardiomegaly was detected in 35% of the cases and gastrointestinal megasyndromes in 7%. Benznidazole was the treatment of choice in 44% of the cases. The mortality rate was of 27%. The conducted systematic review provides valuable information about Chagas disease published cases. From our knowledge, we are the firsts to report how its trends and behaviors have been presenting around the world through the last century, as most of its previous data came from specific regions. We consider that case reports represent a great opportunity for clinicians to learn from others experience, and that by understanding the past and current epidemiology of the disease we can develop a better approach to handle it.

1981

CHAGAS DISEASE AND MEXICAN IMMIGRANTS LIVING IN SOUTHERN CALIFORNIA

Alba R. Valdez-Tah

University of California, Irvine, CA, United States

Chagas disease (CD) affects the Mexican population on both sides of the Mexican-U.S. border. Mexicans are the largest Latino population in the U.S., among whom are an estimated 360,000-plus cases of CD. The persistence of CD is linked to sociocultural, economic, and political processes in immigrant's origin countries but in the United States as well. This study examines the experience of Mexican CD patients' living in Southern California regarding CD health programs, coping with diagnostic and treatment in the U.S., and retrospectively while living in Mexico. Thus far, 4 women, and 3 men adult Mexican born immigrants with a positive diagnostic for *Trypanosoma cruzi* have been interviewed while data collection is ongoing. Patients live in LA area, and attend the Center of Excellence for CD. I expect to include the analysis of another 10-20 interviews with patients by the time of the presentation. Preliminary qualitative analysis utilized MAXQDA 12. Participants in Mexico were prevented from any information, testing and treatment for CD. Those living in rural communities in Mexico confronted major barriers to health care due to the limited health infrastructure, poverty, and absence of health transportation. They infection status was unbeknown at the moment of the migration, and they have little or no knowledge about the disease. In the U.S., health care access substantially varies by insured and uninsured patients being more vulnerable the undocumented due to their additional low-income, and lack of knowledge of health programs. All patients confront barriers for CD that are transversal through the entire health care system in both countries. CD's low political priority in both Mexico and the U.S. is experience by patients thought the lack of knowledge about CD among physicians and health providers, complete absence of testing and treatment, bureaucratic obstacles, and long wait periods to access those procedures. In the interest of supporting the prosperity of both nations is important to address a binational program for CD that enhance health not only as an individual human right but also as a collective wellbeing that oversteps political borders.

1982

GEOSPATIAL-TEMPORAL DISTRIBUTION OF TEGUMENTARY LEISHMANIASIS IN COLOMBIA (2007 - 2016)

Giovanny Herrera[1], Aníbal Teherán[2], Iván Pradilla[3], Mauricio Vera[4], Juan David Ramírez[1]

[1]Grupo de Investigaciones Microbiológicas - Universidad del Rosario, Bogota, Colombia, [2]Fundación Universitaria Juan N Corpas, Bogota, Colombia, [3]Grupo NeURos, Universidad del Rosario, Bogota, Colombia, [4]Ministry of Health and Social Protection, Bogota, Colombia

Tegumentary Leishmaniasis (TL) is a neglected disease with worldwide distribution and considered a public health problem, especially in Latin America. In Colombia, the governmental epidemiological surveillance system (SIVIGILA) is responsible for collecting information on the presentation of cases of TL from each of the municipalities and departments. In absence of a study compiling and analyzing currently available metadata of TL in Colombia, this study evaluates the geospatial-temporal distribution of TL and identifies the regions of the country on which prevention measures should be established in order to control the disease. This is an exploratory descriptive analysis of the distribution of TL in Colombia. Information was collected on new cases of the disease during the years 2007-2016 from the Colombian reporting system (SIVIGILA). Incidence calculations were made based on population estimates by departments and biogeographical regions. Time evolution is shown in biennial maps. A 10-year series was analyzed, showing that the Amazon region is the most affected in terms of incidence, while the Andean region has the highest number of cases with a high variability among the departments that make it up. In those departments where there is a greater reported diversity of vector species, a large number of cases was observed. Transmission dynamics of TL in Colombia in the past 10 years have been variable, with a greater concentration of cases in the central and southern departments. The present study contributes to improve the understanding of the patterns of distribution of TL in Colombia and can be a basis for future studies of impact evaluation of Health policies in the country and the region.

1983

THE PROBLEM OF HUMAN AND EQUINE AFRICAN TRYPANOSOMIASIS: THE ARMY MEDICAL VETERINARY CORPS AND THE ROYAL ARMY MEDICAL CORPS IN THE AFRICAN CAMPAIGNS DURING THE GREAT WAR

Valerie Adams[1], David Adams[2], Colette Ryset[3], Jessmarie Gonzalez[3], Autumn Davis[4], Femi Taiwo[5]

[1]Georgia Southern University, Statesboro, GA, United States, [2]Point University, Savannah, GA, United States, [3]South University, Savannah, GA, United States, [4]Kennesaw State University, Kennesaw, GA, United States, [5]Texas A & M University, College Station, TX, United States

The Boer War provided a training ground for the use of veterinarians during the Great War a decade and a half later. During the war in South Africa, only about 130 civilian veterinary contractees were responsible for more than 300,000 horses. Indeed, the experience there provided an important impetus in the creation of the Army Veterinary Medical Corps (renamed the Royal Army Veterinary Corps in November 1918) during the interwar years. Drawing on their experiences in the Boer War, human and veterinary medical officers in the African campaigns of 1914-1918 once again faced trypanosomiasis, one that struck humans and horses alike. The need for qualified veterinarians was obvious: Cavalry without healthy light-draught horses or at-the-ready heavy-draught horses to haul supply wagons and artillery found their battle-readiness significantly compromised. Moreover, stricken cavalrymen were of little use against the enemy. This presentation, based on archival materials and contemporary accounts from the Great War, examines the devastating impact of African trypanosomiasis on African- Campaign horses and men and the efforts of practitioners to control the disease.

1984

CARRIAGE RATES OF *TRYPANOSOMA CRUZI* AMONG KISSING BUGS (*TRIATOMA* SPP.) IN SOUTHERN ARIZONA

Norman L. Beatty[1], Nicole Behrens-Bradley[2], Maria Love[2], Shannon Smith[1], Justin O. Schimdt[3], Patricia L. Dorn[4], Nafees Ahmad[2], Stephen A. Klotz[1]

[1]University of Arizona College of Medicine, Department of Medicine, Division of Infectious Diseases, Tucson, AZ, United States, [2]University of Arizona College of Medicine, Department of Immunobiology, Tucson, AZ, United States, [3]Southwestern Biological Institute, Tucson, AZ, United States, [4]Loyola University New Orleans, Department of Biological Sciences, New Orleans, LA, United States

The three predominant triatomine species found in southern Arizona (*Triatoma rubida*, *T. protracta*, *T. recurva*) are known to harbor *Trypanosoma cruzi*, the causative agent of Chagas disease. We analyzed 219 triatomines for carriage of *T. cruzi* (*T. rubida*, N=114; *T. recurva*, N=87; *T. protracta*, N=18). These triatomine specimens were provided from our citizen science program and field collections from Tucson, Arizona and surrounding regions in southern Arizona. The distal two-thirds of the intestinal tract of each insect were isolated during hindgut dissection and DNA extraction was performed according to the manufacturer's protocol (Qiagen DNeasy® Blood & Tissue Kit). The DNA was then amplified by RT-PCR using the *T. cruzi*–specific primers TCZ1 and TCZ2. *Triatoma rubida* and *T. protracta* needed annealing temperatures of 57°C for 15 to 30 seconds and *T. recurva* required an annealing temperature 58°C for 30 seconds for amplification of these sequences. All PCRs were run with a positive control, which consisted of purified *T. cruzi* DNA and a negative control of H_2O. *Trypansoma cruzi* was present in 28.8% (63/219) of the total tested triatomines (41.2% (47/114) *T. rubida*; 22.2% (4/18) *T. protracta*; 13.8% (12/87) *T. recurva*). Among those triatomines that we could sex, 34.3% (24/70) of male and 29.3% (27/92) of female specimens were positive; nymphal stages were 21.1% (12/57) positive. Interestingly, 54.7% (29/53) of *T. rubida* collected from the most populated region of southern Arizona (Tucson) were positive. *Trypansoma cruzi* is common among the triatomines that naturally inhabit southern Arizona. Carrier rates were nearly two-fold higher among *T. rubida* compared to *T. protracta* and *T. recurva*, but not significantly different among male, female, and nymphal stages. This is the largest analysis to date utilizing molecular techniques to assess the incidence of *T. cruzi* carriage among triatomines in southern Arizona. Further studies are needed to better understand the risk and potential transmission of *T. cruzi* to humans in this region.

1985

A CROSS-SECTIONAL STUDY OF CHAGAS DISEASE AND VECTOR EXPOSURE IN A HIGH-RISK POPULATION OF TEXAS HUNTERS

Sarah M. Gunter[1], Micaela Sandoval[2], Kimberly Coffman[2], Shannon E. Ronca[1], Rodion Gorchakov[1], Lauren Leining[1], Kristy O. Murray[1], Melissa S. Nolan[1]

[1]Baylor College of Medicine, Houston, TX, United States, [2]The University of Texas Health Science Center, Houston, TX, United States

Chagas disease, caused by the protozoan parasite *Tyrpanosoma cruzi*, remains one of the most significant neglected tropical diseases affecting the Americas. It is estimated that 6 to 8 million people are infected with this parasite worldwide, with 300,000 living in the United States. This disease causes progressive cardiac damage in about 30% of infected people, resulting in significant morbidity and mortality. Symptomatic cardiac disease does not usually develop until decades after the initial infection. Initial stages of Chagas disease are typically asymptomatic, making it difficult to detect cases early when the treatment is most effective. Therefore, identifying high-risk populations is important for understanding Chagas disease transmission and directing public health resources. We have recently identified that Texas hunters may be at elevated risk for contracting Chagas disease due to their extended amount of time spent outdoors and frequent contact with wildlife. To assess their exposure to *T. cruzi* and the arthropod vectors we began a state-wide screening program. Through our recruitment efforts at public hunting areas, private hunting organizations, and hunting expos we have been able to enroll over 1,000 hunters for this study. For each participant, we have conducted a risk-factor interview and collect a blood sample to assess disease status and exposure frequency to wildlife reservoirs and vector species. This large-scale screening program represents a novel approach to better understanding Chagas disease transmission and vector exposure in this high-risk population in the southern United States.

1986

TRYPANOSOMA CRUZI IN DOMESTIC AND WILD RESERVOIRS OF THE DEPARTMENT OF CÓRDOBA

Catalina Tovar Acero[1], Dina Ricardo Caldera[1], Lyda Espitia Perez[1], Julio Chacón[2], Miguel Doria[3]

[1]Universidad del Sinú, Montería, Montería, Colombia, [2]Universidad de Córdoba, Montería, Montería, Colombia, [3]Fundación Colombia Mia, Montería, Montería, Colombia

Introduction: T. cruzi reservoirs can act as a source of infection for animals, vectors, and humans contributing to the establishment of Chagas disease (CD) in a particular area. The department of Córdoba was not considered as a transmission area for CD; however, during the last years the report of several acute cases of the disease have motivated the study of a new transmission scenario for this region. In consequence, this study aimed to detect T. cruzi in domestic and wild reservoirs of the department of Córdoba. Materials and methods: During September 2016 and July 2017, a descriptive cross-sectional study was conducted in 4 villages of the municipality of San Andrés de Sotavento and two villages of the municipality of Sahagún. Blood samples from canines living in the zone were collected in EDTA vacutainer tubes after obtaining an informed consent from their owners. Wild reservoirs were capture using Sherman, Tomahawks traps and bats mist nets. T. cruzi DNA was detected using kDNA and the tandem repeat region as molecular targets. SL-IR was used as a molecular marker for detection of the lineage. Results: 168 canines and 146 wild mammals were included in the study, 114 individuals of the order Chiroptera, 12 individuals of the order Rodentia, 20 individuals of the order Didelphimorphia. The most abundant species was G. soricina with 17,1 % of the total individuals captured, followed by the species D. marsupialis with 13,0%. T. cruzi DNA was detected in one canine from Villa Lucía and in 13.0% of wild animals; 16 D. marsupialis, 2 H. anomalous and one A. planirostris. The TcI lineage was found in 12 D. marsupialis, 2 H. anomalous and one canine. One specimen of D. marsupialis with TcI and TcII lineages was also identified. Conclusions: T. cruzi DNA was detected in domestic and wild animals in the studied municipalities, indicating the circulation of the parasite in peridomiciliary environments. D. marsupialis presented the highest percentage parasites, representing an important reservoir candidate in the maintenance of the wild and domestic cycle in this geographical area.

1987

PREVALENCE AND RISK FACTORS OF CHAGAS DISEASE AMONG AGRICULTURAL WORKERS IN NORTHWESTERN NICARAGUA

Megan L. McKenna[1], Sarah Gunter[1], Melissa Nolan[1], Rebecca S. Fischer[1], Denis Chavarria[2], Lesbia Palma[2], Kristy O. Murray[1]

[1]Baylor College of Medicine, Houston, TX, United States, [2]Gerencia de Salud Ocupacional, Ingenio San Antonio, Nicaragua Sugar Estates Limited, Chichigalpa, Nicaragua

Chagas disease is an infection caused by the parasite, *Trypanosoma cruzi*, and is primarily transmitted to humans by Triatomine insects. This disease is endemic throughout the Americas, and it is estimated that 6-8 million persons are infected. Thirty percent of those infected are likely to develop

Chronic Chagas Cardiomyopathy (CCC), a rapidly, progressive form of cardiomyopathy. CCC is the most common cause of heart failure in Latin America, and sudden cardiac death is the most common presenting symptom. Nicaragua is a country that historically has had a high burden of Chagas disease. Despite the formation of vector control programs, there is evidence of sustained transmission among its inhabitants, but there is limited published literature available on the current prevalence of Chagas disease in northwestern Nicaragua. Given concerns for continued transmission and vector exposure, the prevalence and risk factors among northwestern agricultural workers was assessed. Using rapid diagnostics (chromatographic immunoassays), the prevalence of Chagas disease was found to be 1.6%. There was no statistical significance between those infected and uninfected based on age (≤21yo and ≥38yo), gender, or working in an indoor or outdoor environment. However, given the recent vector control programs, the lack of statistical significance of infection between the younger and older groups raises concern of ongoing transmission among this population. Further prevalence studies and risk factor assessment is needed to determine the current risk of Chagas disease among different populations in northwestern Nicaragua.

1988

DECREASING THE IMPACT OF CHAGAS DISEASE THROUGH MODELLING: THE DICTUM FRAMEWORK FOR RETRIEVING, COLLATING, AND ANALYSING SEROSURVEY DATA FOR CHAGAS DISEASE ACROSS LATIN AMERICA

Julia B. Halder[1], Denys Prociuk[1], Pierre Nouvellet[2], Maria-Gloria Basáñez[1], Zulma M. Cucunubá[1]

[1]Imperial College London & London Centre for Neglected Tropical Disease Research, London, United Kingdom, [2]University of Sussex, Brighton, Imperial College London, & London Centre for Neglected Tropical Disease Research, London, United Kingdom

In order to assess progress towards interruption of intra-domiciliary transmission of *Trypanosoma cruzi* in the 21 endemic countries of Latin America, understanding the historical exposure to infection is paramount. Serological surveys can provide useful insight: if the data are age-structured, the force-of-infection (FoI) can be estimated retrospectively according to the ages of the serosurvey participants. Following from previous analyses of data from Colombia, which allowed understanding of the spatio-temporal profiles of the FoI, we expand this work across Latin America to support the endemic countries' goals. The first stage was to search published literature and construct a framework for collating and harmonising serological survey data and preparing these for modelling the FoI. We constructed a comprehensive search for PubMed, Embase, LILACS, Global Health, CAB Abstracts and Web of Science, to find published data for the endemic countries. Gaps in the published, retrievable literature were identified. We constructed standardised data extraction forms and collated data for a subset of these countries. The serosurvey results were harmonised and stored, with survey and source meta-data, in a relational database. The total number of serosurveys stored after screening and elimination of literature as of March 2018 is 241. This includes, from 3421 search results for these countries: from Brazil: 27; Argentina: 48; Mexico: 31; Bolivia: 19; Central America: 7 (Guatemala: 6; Costa Rica: 1), alongside 109 datasets from the Colombia work, which were collated from published and unpublished literature. Of note, Central American countries have a paucity of published data. There are 116 datasets from rural areas, 44 from urban, 32 from mixed settings or setting not ascertained from the reference. The database facilitates the retrieval of data for use in catalytic models to reconstruct estimates of the FoI through time and space. Model outputs, primarily the FoI estimates, are also stored in the database ready for further analyses such as obtaining estimates of disease burden.

1989

COMPARISON OF COSTS BETWEEN TWO STRATEGIES OF ACTIVE CASE FINDING OF HUMAN AFRICAN TRYPANOSOMIASIS IN THE DEMOCRATIC REPUBLIC OF THE CONGO

Rian Snijders[1], Alain Fukinsia[2], Yves Claeys[1], Epco Hasker[1], Alain Mpanya[2], Erick Miaka[2], Pascal Lutumba[3], Filip Meheus[4], Marleen Boelaert[1]

[1]Institute of Tropical Medicine Antwerp, Antwerp, Belgium, [2]Programme National de Lutte Contre la Trypanosomiase Humaine Africaine, Kinshasa, Democratic Republic of the Congo, [3]Tropical Medicine Department, Kinshasa University, Kinshasa, Democratic Republic of the Congo, [4]International Agency for Research on Cancer, Lyon, France

Human African Trypanosomiasis (HAT) is a parasitic vectorborne disease that remains a major problem in Sub-Saharan Africa. WHO's goal is the elimination of HAT as a public health problem by 2020. Current control and surveillance activities include case finding, treatment, and tsetse control. These strategies are implemented at different levels and intensity according to the epidemiological situation, the financial resources and the capacity available. Since many years active screening campaigns through truck-based mobile teams are the main control strategy for endemic areas. A more intense deployment of the right mix of strategies and sustained funding will be needed to achieve HAT elimination. Today only limited information is available to estimate the related costs. In 2015 a project started to eliminate HAT in two endemic health zones in the Democratic Republic of the Congo. One of the main activities was the expansion of the active screening capacity through the introduction of motorcycle based "mini" teams using an adapted screening algorithm. Both the classical and the mini-teams have a screening capacity of 60,000 to 70,000 people annually. The aim of this study is to estimate the costs of both strategies from a healthcare provider perspective. We combine several costing methods, including bottom-up costing and gross-costing. Sensitivity analysis is conducted on key parameters which could affect the results, such as the price of inputs and screening capacity to examine the robustness of the results. The preliminary results show that the average cost per person screened and per person diagnosed for a mini-team is lower (1.12$/person screened) than for a classical team (1.40$/person screened) excluding programmatic costs. We will present a detailed breakdown of the factors that influence these costs and discuss their importance under different scenarios, such as the type of screening algorithm, varying disease prevalence and inefficiencies in resource use for diagnosis. Our data allow for estimating the economic costs of HAT screening campaigns and will contribute to rational decision making in HAT control and elimination programs.

1990

THE VALUE OF HAT STAGING BEYOND TREATMENT

Cody A. Palmer, Caitlin A. Bever

Institute For Disease Modeling, Bellevue, WA, United States

Gambiense Human African Trypanosomiasis (gHAT) is rapidly approaching elimination as a public health problem in many of its endemic areas. As active screening efforts are reduced, control programmes are compelled to extract more information from a smaller set of epidemiological data. gHAT infections progress through two biologically distinct stages, with the transition from the first to the second marked by trypanosome infiltration of the cerebrospinal fluid. While stage information has traditionally only been used for treatment purposes, the incidence ratio of the two stages has been conjectured to contain useful information regarding undetected cases, the impact of interventions, and proximity to disease elimination. However, there remains much work to be done in bridging the gap between conjecture and application. In order to bring the stage ratio into the operational space for gHAT control, elimination, and surveillance, a detailed analysis of stage ratio behavior is needed. Through mathematical models of gHAT epidemiology, we explored how differences in near-

elimination scenarios would be borne out in measurements of the stage ratio, with attention given to potential uncertainties such as importation rates and the presence of asymptomatic cases. Based on the simulations, we determined what epidemiological conclusions can be reliably drawn from a given observation of the stage ratio, and identify any additional data sources that might narrow the range of transmission intensities consistent with the measurements. These results form the basis for recommendations to assist national control programmes in their ability to assess the need for sustained, decreased, or increased interventions. The value of this framework will be demonstrated by applying it to traditionally under-screened, HAT-endemic areas in Eastern Democratic Republic of the Congo that are thought to be near elimination.

1991

INVESTIGATING THE GENETIC DIVERSITY OF *TRYPANOSOMA CRUZI* FROM *PROCYON LOTOR* IN LOUISIANA USING A NEXT-GENERATION SEQUENCING APPROACH

Alicia Majeau[1], Nikki Anderson[2], Gary Balsamo[3], Dawn Wesson[1], Eric Dumonteil[1], Claudia Herrera[1]

[1]Tulane University, New Orleans, LA, United States, [2]Louisiana Department of Wildlife and Fisheries, Baton Rouge, LA, United States, [3]Office of Public Health, Louisiana Department of Health, New Orleans, LA, United States

Trypanosoma cruzi, the causative agent of Chagas disease, is a protozoan parasite with complex transmission patterns and considerable genetic diversity represented by seven stable genetic lineages, known as discrete typing units (DTUs) named TcI-TcVI and TcBat. As *T. cruzi* can infect a broad range of mammalian hosts, enzootic cycles involving peridomestic animals may pose a spillover risk to humans. Local transmission has been demonstrated in the southern United States in recent years, highlighting the need for investigation into prevalence and transmission patterns to fully assess risk and plan control measures. Raccoons (*Procyon lotor*) are a particularly important reservoir to investigate in terms of *T. cruzi* infection in the United States due to their close association to human habitats, relatively high parasite prevalence, high parasitemia, and high infectiousness index. Previous investigations have reported the circulation of TcI and TcIV in raccoons in the US, but have faced genotyping limits inherent to Sanger sequencing methods, which fail to detect mixed infections and accurately capture the scope of parasite diversity. We tested heart and colon samples from 71 raccoons trapped across six parishes in Louisiana via polymerase chain reaction using primers targeting *T. cruzi* satellite DNA, resulting in a prevalence of 23.9% (17/71). Primers targeting a 500-bp mini exon region were then used to amplify DNA for next-generation sequencing and phylogenetic analysis. We predominantly identified TcI followed by TcIV in these raccoons. However, multiple haplotypes were found in most animals, including mixed infections with TcI and TcIV, highlighting the sensitivity of our methods to detect *T. cruzi* diversity in hosts and suggesting polyclonal infections. These results confirm the high infection rate in raccoons in the region, and programs to control *P. lotor* reservoirs may prove important to human health.

1992

COMPANION DOGS LIVING IN UNDERSERVED COMMUNITIES ALONG THE US MEXICO-BORDER SERVE AS RESERVOIR HOSTS FOR *TRYPANOSOMA CRUZI*, AN INCREASING PUBLIC HEALTH THREAT

Italo B. Zecca, Lisa D. Auckland, Ester Carbajal, Sarah Hamer

Texas A&M University, College Station, TX, United States

Chagas disease is caused by the zoonotic parasite *Trypanosoma cruzi* and transmitted by triatomine vectors; the parasite affects 8 million people worldwide. While high quality housing in the southern US generally prohibits colonization by triatomines, there are focal areas in which domestic infestations can occur, including in impoverished and underserved communities along the Texas-Mexico border (colonias). We previously detected a low prevalence of autochthonous human infections in colonias. In the current study, we expanded surveillance for *T. cruzi* infection in companion dog populations living in Texas colonias. We hypothesized that these dogs are highly exposed given that animals in colonias receive little to no veterinary care and typically live a free-range lifestyle. In summer and fall of 2016-2017, a cross-sectional study was conducted to quantify the prevalence of *T. cruzi* exposure among owned dogs. Through the aid of a promotora (a culturally-competent community health worker), we conducted door-to-door outreach and collected blood samples from dogs with informed owner consent. Through serological testing of 231 canines, we identified 82 (35.5%) positive individuals confirmed by at least two independent antibody detection platforms; this seroprevalence is markedly higher than that which we previously found in shelter (18%) and working (19%) dogs across the state. Dogs sampled in the fall were twice as likely to be seropositive than those in summer ($P<0.01$), likely due to time needed to develop antibodies following exposure during the peak summer activity period of vectors. Parasite DNA was detected in 6 (2.6%) of the dogs, indicative of a circulating infection. The subset of these dogs from which we determined parasite strain were infected with 'TcI', the *T. cruzi* strain associated with autochthonous human disease in the US. Domestic dogs living in colonias may serve as reservoirs to infect vectors in proximity to colonia residents, potentially increasing the risk of vector-borne transmission. Under a one-health framework, the identification of local reservoirs is a key component in developing public health interventions.

1993

ASSESSING BEHAVIORAL RISK FACTORS FOR DISEASE TRANSMISSION AT THE HUMAN-ANIMAL INTERFACE IN LAIKIPIA COUNTY, KENYA - 2017

Lindsey M. Shields[1], Joseph Kamau[2], Peris Ambala[2], Allan Kwallah[3], Elizabeth Ashby[4], Megan Vodzak[1], Suzan Murray[1], Dawn Zimmerman[1]

[1]Smithsonian Institution, Washington, DC, United States, [2]Institute of Primate Research, Nairobi, Kenya, [3]Kenya Medical Research Institute, Nairobi, Kenya, [4]George Mason University, Fairfax, VA, United States

Human behaviors can drastically affect the risk of disease transmission between humans and animals such as anthrax, brucellosis and rabies. Understanding the cultural and behavioral risk factors in a community can therefore inform effective educational and intervention campaigns to minimize zoonotic disease transmission. We interviewed 156 persons living, working, or visiting two areas with high levels of human-animal contact in Laikipia County, Kenya, using cluster sampling from community-based recruiting. We interviewed 100 (64%) persons at Lekiji and 56 (36%) persons at Mpala, both villages with human-livestock-wildlife interfaces. We asked questions about demographic characteristics, indirect human-animal contact through water and food sources, human-animal interactions, and health status. Interviewed persons ranged in age from 11 to 84 years (median 28 years); 63 (40%) were male, and 151 (97%) reported handling live animals within the last year. Of 121 adults interviewed, 48 (40%) had received no formal education. The majority (67%) of respondents sourced drinking water from unimproved water sources, and 115 (74%) shared their drinking water with animals. Individuals who shared their water with animals were less likely to treat their drinking water (OR = 0.29, $p<0.05$) than those who did not share their water. Fifty-two percent of respondents reported eating a sick animal in the previous year, and 44% reported consuming meat from an animal found dead. Males were more likely than females to have slaughtered animals (OR = 2.4, $p<0.05$) and to have eaten raw meat (OR=2.5, $p<0.05$) in the last year. Ninety percent of respondents were worried about disease and disease outbreaks in live animals at local markets. Although respondents were concerned about disease transmission, safe practices in water, food, and animal handling to decrease risk were not commonly used. Educational messaging through trusted community leaders and community groups should target individuals at higher risk for disease transmission.

1994

DO SPOROTRICHOSIS ETIOLOGICAL AGENTS EQUALLY DISPLAY POTENTIAL VIRULENCE ATTRIBUTES?

Pâmella A. Macêdo-Sales[1], Ricardo Luiz D. Machado[1], Lucieri O. Souza[2], Simone R. Souto[1], Leila Maria Lopes-Bezerra[3], Elisabeth M. Rocha[1], Hector M. Mora-Montes[4], Andre Luis S. Santos[2], **Andrea Regina S. Baptista**[1]

[1]Universidade Federal Fluminense, Niteroi, Brazil, [2]Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil, [3]Universidade do Estado do Rio de Janeiro, Rio de Janeiro, Brazil, [4]Universidad de Guanajuato, Guanajuato, Mexico

Since the mid-90s, Rio de Janeiro, Brazil, faces an epidemic scenario of sporotrichosis, a neglected zoonosis caused by pathogenic dimorphic fungi of the *Sporothrix* genus. *Sporothrix* adaptation to both saprophytic and parasitic lifestyles requires a set of survival skills in extremely different conditions. To describe and compare *in vitro* virulence attributes of culture collection as well as of clinical strains obtained from infected cats in the State of Rio de Janeiro, Brazil, yeasts, conidia and mycelia of three reference strains (*S. schenckii stricto sensu*- Ssch; *S. globosa* - Sglo and *S. brasiliensis*- Sbra) as well as eight *S. brasiliensis* clinical isolates (SbraC) were investigated. *S.glo* was not able to display hemolytic activity or phospholipase production. All other species/strains were able to produce protease and hemolityc activity. All *S. brasiliensis* produced phospholipase, while esterase was produced solely for those obtained from feline infection. Phytase production was not detected. *S. brasiliensis* hydrophobicity of conidial and yeast forms were higher than *S. schenckii*. Conidia size did not differ among *Sporothrix* species, while granularity showed great variation within species. As for the parasitic phase, both parameters were different among the three species. Yeasts and mycelia from all the studied strains formed biofilm on polystyrene in a typical time-dependent process. The capacity of yeast biofilm formation was different among the species concerning biomass and cell survival. Comparatively, SbraC biomass was smaller than obtained for the Sbra strain on polystyrene, however clinical isolates proven to be more able to survive on the same conditions. *SbraC* showed wider diversity in enzymatic activity, suggesting a potential role for these enzymes in *S. brasiliensis*-host interaction. In addition, although composed of lower biomass, clinical isolates of this species formed biofilms in polystyrene with higher cell survival rates. Our results add data to the understanding of *S. brasiliensis,* the most prevalent species in the Brazilian feline sporotrichosis epidemics, major adaptations to the vertebrate hosts.

1995

ZOONOTIC THREATS OF MONGOLIAN HERDING HOUSEHOLDS: A ONE HEALTH APPROACH TO IDENTIFYING RISK FACTORS AND DISEASE PERCEPTIONS

Amber N. Barnes[1], Uyanga Baasandagva[2], Anu Daavasuren[2], Battsetseg Gonchigoo[2], Gregory C. Gray[1]

[1]Duke University, Durham, NC, United States, [2]Institute of Veterinary Medicine, Ulaanbaatar, Mongolia

Mongolian herding families live in close proximity to livestock and rely on animals for meat, milk, fur, hide, transportation, sport, culture, and income. However, this contact puts herders and their families at risk for zoonotic disease exposure. In order to understand the this herder-livestock relationship within a larger One Health framework, a comprehensive survey was conducted in 250 rural, peri-urban, and urban households across Selenge, Zavkhan, Dundgovi and Tov provinces to identify household animal contact, water, sanitation, and hygiene behaviors, gender roles and responsibilities related to animal husbandry and herding, animal and human diarrheal disease history, and zoonotic knowledge, attitudes, and risk perception. From our results, we found that animal contact at households occurs frequently (n=149) and almost all rural and many peri-urban households reported animal ownership, particularly with dogs (n=166), sheep (n=149), goats (n=148), cows (n=137), and horses (n=135). Animal husbandry practices were shared among men and women for herding, feeding livestock, assisting with sick animals, and tending to births. However, gender roles were apparent in other chores with males performing home slaughter and butcher and women in charge of the milking and cooking. Most study households lived in a ger (n=167) and the majority reported having a dedicated hand washing area at their home (n=147). Over 90% of households wash their hands after animal contact (n=136). And despite an overall knowledge (83%) of disease transmission from animals to humans (n=207), there was a gap in recognizing that humans can transmit disease to animals, or reverse zoonosis (n=21). The majority (82%) of households believe that animal contact presents a disease risk for humans (n=204) but most do not believe that it is possible to avoid animal contact as a zoonotic prevention method (n= 39). The relationship between Mongolian nomads and their animals is unique and future One Health education and interventions to make their human-animal interface healthy and safe should be tailored to the distinct needs of each herding community.

1996

COMPARING SURVEYS ON TICK BITE HISTORY TO EVIDENCE OF TICK-BORNE DISEASE EXPOSURE AMONG NOMADIC MONGOLIAN HERDERS

Kathryn M. Hogan[1], Sukhbaatar Lkhagvatseren[2], Bazartseren Boldbaatar[2], Ben Anderson[3], Laura Pulscher[3], Gregory C. Gray[3], Michael E. von Fricken[1]

[1]Department of Global and Community Health, George Mason University, Fairfax, VA, United States, [2]Institute of Veterinary Medicine, Ulaanbaatar, Mongolia, [3]Division of Infectious Disease, Duke Global Health Institute, Duke University, Durham, NC, United States

Twenty-six percent of Mongolians live pastoral lifestyles, increasing their likelihood of exposure to ticks and placing them at a higher risk for contracting tick-borne diseases (TBDs). *Anaplasma* spp. and *Rickettsia* spp. have been identified in ticks, wildlife, and humans in Mongolia, but no known qualitative research has been conducted investigating the association between nomadic herder characteristics, tick bite history, and exposure to TBDs. To better understand the association between self-reported tick bites and symptoms versus actual exposure to TBDs, this study paired serological data with 335 administered surveys from 2014 to 2015. Results identified some similar trends in reporting of tick bites and actual exposure to TBDs, with significantly more reports of tick bites among men than women ($\chi^2 = 4.77$, $p = 0.029$), and increased exposure to either *Anaplasma* spp. or *Rickettsia* spp. among men ($\chi^2 = 5.25$, $p = 0.022$). However, results also identified inconsistencies in reporting and seroprevalence among different age groups, with children having the highest reporting and treatment seeking rates but low levels of exposure in comparison to other groups. While survey results showed that individuals were aware of peak tick seasons and tick species that inhabit specific areas, 58% of heads of households (49/84) were unaware that ticks can cause disease in livestock or dogs. This study suggests that herders are an at-risk population in Mongolia with gaps in awareness of TBD risk. Increased surveillance paired with focused outreach to prevent TBDs targeted to the herder population is encouraged.

1997

THE COEVOLUTION EFFECT: A HYPOTHESIS TO EXPLAIN ZOONOTIC PATHOGEN SPILLOVER

Sarah Zohdy, Tonia S. Schwartz, Jamie R. Oaks

Auburn University, Auburn, AL, United States

Global habitat loss has led to the emergence of infectious diseases (EIDs) of wildlife origins into human. Despite this well accepted narrative, the mechanisms driving the association between habitat degradation and disease emergence remain unclear. A novel hypothesis, the Coevolution Effect, is proposed here to explain the underlying eco-evolutionary mechanisms at the population level driving EIDs. Evoking theories of island

biogeography, specifically, testing whether loss of habitat connectivity creates multiple coevolutionary engines that generate increased pathogen diversity across the landscape. The engines are isolated within habitat fragments with independent evolutionary trajectories comprising wildlife hosts, obligate parasite vectors (e.g., lice, batflies), and their coevolving microparasites. When combined with bridge vectors (e.g. mosquitoes, ticks) this coevolutionary feedback loop will cause increased opportunity for spillover of unique pathogens into human communities, and the potential for any one of them to induce an outbreak. To test the Coevolution Effect hypothesis, it is ideal to work in paired regions of high and low forest connectivity, the researchers will (1) integrate landscape genomics and demographic modeling to determine the effect of forest connectivity on the population structure of wildlife host and obligate parasite vectors; (2) characterize pathogen diversity in species across the landscape and target pathogen lineages within hosts and parasites to test for a relationship between the degree of habitat connectivity and pathogen genetic diversity using phylogenetic models; and (3) use targeted pathogen metagenomics to test the Coevolution Effect, specifically, if mobile bridge vectors like mosquitoes can mobilize the new pathogen genetic variants from the wildlife- parasite coevolutionary engines into human communities.

1998

ANTIMICROBIAL SUSCEPTIBILITY OF *ARCOBACTER*, AN EMERGING ZOONOTIC PATHOGEN ISOLATED FROM FECAL HUMAN AND ANIMAL SAMPLES (CATTLE AND PIGS)

Rito Zerpa[1], Jorge O. Alarcón[1], Debora E. Alvarado[2], Astrid A. Laguna[3], Elizabeth A. Ortega[3], Javier O. Soto[4]

[1]Instituto de Medicina Tropical, Lima, Peru, [2]Biology Faculty, San Marcos University, Lima, Peru, [3]Faculty of Medicine, San Marcos University, Lima, Peru, [4]Instituto Materno Infantil San Bartolomé, Lima, Peru

Few reports of evidence of antimicrobial susceptibility of *Arcobacter spp.* have been published worldwide and no reports yet exist for Peru. To know the antimicrobial susceptibility of *Arcobacter*, an emerging zoonotic pathogen isolated from fecal human and animal samples (pigs and cattle). Antimicrobial susceptibility tests were carried out with 20 strains of human fecal samples and animals, using E-test for the determination of the minimum inhibitory concentration (MIC) and the disc-diffusion method with 90 strains. *Arcobacter* was isolated 7 fecal samples of children from the National Institute of Child Health and the Maternal and Child Hospital of San Bartolomé. 83 strains were isolated from fecal samples of animals (pigs and cattle) from the La Colonial SAC refrigerator. In the antimicrobial susceptibility tests with E-test, we worked with 20 isolates of *Arcobacter*: 7 human fecal samples and 13 animals, with 5 antimicrobials: erythromycin, ciprofloxacin, tetracycline, ampicillin and nitrofurantoin; we found with erythromycin MIC_{50} and MIC_{90}, 2ug / ml and 32ug / ml respectively (15% resistance); with ciproploxacin, CIM_{50} and CIM_{90}, 0.75ug / ml and 16ug / ml respectively (20% resistance); with tetracycline: CIM_{50} and CIM_{90}, 8ug / ml and 32ug / ml respectively (35% resistance); with ampicillin, CIM_{50} and CIM_{90}, 2ug / ml and 38ug / ml respectively (25% resistance); with nitrofurantoin CIM_{50} and CIM_{90}, 8ug / ml and 96ug / ml respectively (25% resistance). In the disk-diffusion antibiogram of 90 isolates resistance was found: erythromycin 3.3%, ciprofloxacin, 11.1% tetracycline 58.8%, ampicillin 45.5% and with nitrofurantoin 18.8%. For the first time in Peru, results of antimicrobial susceptibility tests of *Arcobacter* isolated from human fecal samples and animals are presented here. These results show a high resistance of *Arcobacter* with ampicillin and tetracycline and low percentage resistance with erythromycin and ciprofloxacin 3.3% and 11.1% respectively; and with nitrofurantoin 18.86%; these are useful data to improve its control and adoption of preventive measures to infections in humans and in animals of popular consumption.

1999

COXIELLA BURNETII WITHIN SMALL LIVESTOCK HERDS IN AN AREA OF SEDENTARY PASTORALISTS IN LAIKIPIA, KENYA: HERDING BEHAVIORS, SOCIOECONOMICS AND SEROPREVALENCE

Peter S. Larson[1], Rebecca Hardin[1], Johannes Foufopoulos[1], Christine A. Wang[1], Leon Espira[1], Eric Fevre[2], Springer Browne[3], Joseph N. Eisenberg[1]

[1]University of Michigan, Ann Arbor, MI, United States, [2]International Livestock Research Institute, Nairobi, Kenya, [3]Massey University, Auckland, New Zealand

Coxiella burnetii is an obligate intracellular bacterial pathogen and the causative agent in Q fever, a disease of livestock and humans. Little is known about how livestock management behaviors among small holder herders might impact risk for disease in East Africa. This research aims to describe the seroprevalence of C. burnetii in goats, sheep and cattle in a small community of sedentary pastoralists in a semi-arid area of Kenya. Researchers were introduced to eligible households through a local intermediary. Teams visited households and obtained permission to collect blood samples from livestock and to administer a survey instrument on livestock management, recent births, deaths and sales of animals, animal health and demographics. Animals were chosen at random with a target number of 15% of the herd or a minimum of 10 animals of each species, whichever was greater. GPS locations of each herd were taken at each location. Blood samples were then tested for presence of IgG antibodies using a commercially available ELISA kit. 28 individual households were surveyed, comprising 426 animals representing goats (262), sheep (91), cattle (55) and camels (18). Of these, 66 (17.5%) were seropositive, with seroprevalence varying by animal species. Within herds, seroprevalence varied, ranging from no animals being found to be seropositive to 40% or all animals being seropositive. Male animals were found to be less likely to be seropositive than females (OR .36 (.24, .95)). Among goats and sheep, risk for seropositivity was lower among households which reported selling animals to buy medications (OR .24 (.09, .63)). Weak, though protective associations were found for calling a veterinarian when animals are ill (OR .42 (.16, 1.09)) and monthly dipping for ticks (OR .53 (.27, 1.04)). Risk for seropositivity was not associated with increased proportions of animal losses (OR 0.28 (.00, 28.6)). Proactive herd management by smallholder livestock herders is associated with decreased risk for herd level infection in goats. Strategies to encourage or support protective practices such as spraying for ectoparasites might help reduce incidence of Q fever in livestock.

2000

CHARACTERIZING THE RISK OF BAT-BORNE VIRUS EXPOSURE AT POPULAR CAVE DESTINATIONS IN SOUTHEAST ASIA FOR PREVENTION AND RESPONSE

Heather S. Davies[1], Alexis C. Garretson[2], Kathryn M. Hogan[3], Faris Naimi[2], Megan E. Vodzak[4], Dawn Zimmerman[4], Marc Valitutto[4], A. Alonso Aguirre[1], Michael von Fricken[3]

[1]Department of Environmental Science and Policy, George Mason University, Fairfax, VA, United States, [2]Department of Biology, George Mason University, Fairfax, VA, United States, [3]Department of Global and Community Health, George Mason University, Fairfax, VA, United States, [4]Global Health Program, Smithsonian Conservation Biology Institute, Washington, DC, United States

Bat-human exposure is a driver of viral disease spillover. Bats were the documented source of Marburg Virus Disease (MVD) contracted by two tourists in 2008 after visiting the Python Cave in Uganda. In Southeast Asia, tourism is increasing steadily, exceeding 100 million visitors in 2015, and cave tours are a popular visitor activity. This study utilized robust surveillance data available for the region to identify risk factors for viral exposure to humans at top cave-tourism destinations. Bat species

that likely roost at these highly-visited caves were determined using range data and local species checklists. Species-specific viral detections proximal to these caves were inventoried from literature and using the Database of Bat-associated Viruses (DBatVir). Detection features relevant to transmission (sample prevalence, seasonality, media presence, and phylogenetic lineages) were identified. Relative risk between the caves was compared using visitation data, roosting ecology and population size, and the prevalence and proximity of bat-virus detections. Over the last 20 years, viruses have been detected in nearly 200 chiropteran species in 40 genra across the target region. The diversity of potential reservoir species present locally at heavily-visited caves were identified. Meta-analysis of transmission-related characteristics related to the bats and viruses enriched the cave-specific EID risk profiles. Disease modelling and localized surveillance of emerging infectious diseases (EID) are advancing the science of global biosecurity and One Health. On a regional scale, location-based risk information that is "actionable" by policy-makers can help advance prevention and response activities locally, travel-related disease surveillance, and for use in attracting innovative private investments that target climate resilience and pandemic prevention.

2001

ONE HEALTH APPROACH AND MOLECULAR EPIDEMIOLOGY OF MELIOIDOSIS IN SOUTHERN THAILAND

Apichai Tuanyok[1], Jedsada Kaewrakmuk[2], Vannarat Saechan[2], Pacharapong Khrongsri[1], Somporn Sretrirutchai[2], Thanaporn Hortiwakul[2], Phuwadol Suwanna[3], Michael H. Norris[1], Yuta Kinoshita[4], Treenate Jiranantasak[1], Mohammad S. Rahman-Khan[1], Sarah Parker[1], Aleeza T. Kessler[1], Chompoonoot Koonrungsesomboon[1], Sarunyou Chusri[2]

[1]University of Florida, Gainesville, FL, United States, [2]Prince of Songkla University, Hatyai, Thailand, [3]Songkhla Zoo, Songkhla, Thailand, [4]Equine Research Institute, Tochigi, Japan

It is well-recognized that melioidosis is endemic in most parts of Thailand. However, the prevalence of melioidosis in humans and animals, and the occurrence of its pathogen, *Burkholderia pseudomallei*, in natural environment of southern Thailand has not been updated for long time. We used "One Health" approach and multidisciplinary research to investigate epidemiology of melioidosis in southern Thailand. We have been collecting *B. pseudomallei* isolates from human and animal cases, and soils in Songkhla Province since January 2014. All culture-confirmed *B. pseudomallei* isolates from patients admitted to tertiary care hospitals in the region were further tested by real-time PCR targeting TTS-1, BTFC/YLF, and LPS genes. We have also investigated the presence of *B. pseudomallei* in soils especially in farming areas and a local zoo where animal cases have been reported. We used standard soil culturing techniques with Ashdown's agar. Suspected *B. pseudomallei* colonies were subjected to further identification by latex agglutination and real-time PCR. We have confirmed at least 209 melioidosis cases from humans, as well as, the presence of *B. pseudomallei* in soils in Songkhla. The infections were most likely seasonal and associated with rainfall. Genetic analysis using multi-locus sequencing typing (MLST) has indicated that most of recent isolates had same STs with those from the Finkelstein's historic collection from southern Thailand a half century ago. Specifically, strains with STs 288 and 84 were frequently found in Songkhla. Interestingly, at least 6 patients were confirmed to be infected by multiple STs suggesting a high genetic diversity of *B. pseudomallei* in natural source of the infections. Strains with ST3 were found in human and animal cases, as well as in the environment. We believe that implementing the "One Health" approach would provide a current situation of *B. pseudomallei* infections in humans and animals, as well as its occurrence in the environment in southern Thailand that forms an integral part of regional threat assessment of Thailand and Southeast Asia.

2002

UNDERDIAGNOSES OF RODENT-BORNE DISEASES IN PATIENTS HOSPITALIZED WITH ACUTE FEVER IN INDONESIA

Usman Hadi[1], Bachti Alisjahbana[2], Dewi Lokida[3], Khie Chen Lie[4], I made Susila[5], Ninny Meutia Pelupessy[6], Tri Wibawa[7], **Herman Kosasih**[8], Emiliana Tjitra[8], Muhammad Karyana[9], Muhammad Husein Gasem[10]

[1]RSUD dr Soetomo, Surabaya, Indonesia, [2]RSUP dr Hasan Sadikin, Bandung, Indonesia, [3]RSU Kab Tangerang, Tangerang, Indonesia, [4]RSUPN dr Cipto Mangunkusumo, DKI Jakarta, Indonesia, [5]RSUP Sanglah, Denpasar, Indonesia, [6]RSUP dr Wahidin Sudirohusodo, Makassar, Indonesia, [7]RSUP dr Sardjito, Yogyakarta, Indonesia, [8]INA-RESPOND, DKI Jakarta, Indonesia, [9]National Institute of Health Research and Development, DKI Jakarta, Indonesia, [10]RSUP dr Kariadi, Semarang, Indonesia

Leptospira spp, *Rickettsia spp*, and Seoul virus are prevalent in rodents in Indonesia. However, the prevalence in humans is not well understood. Few reports on *Rickettsia* and Seoul were based only on serological results. No cases were reported in the annual reports of the Ministry of Health. Clinical presentations of these three diseases vary, from mild to severe or even fatal. Mortality rates range from 1% in Seoul Virus to 5% in *Leptospira* infections. To have a better estimate of the burden of these diseases, an observational study on the etiologies of acute fever requiring hospitalization was conducted at 8 top-referral hospitals in 7 large cities from 2013 to 2016. All patients were monitored during enrollment and follow-up visits (14-28 days and 3 months after enrollment). Demographic, clinical data, and blood were collected during each visit. Molecular and serological assays to each pathogen were performed. From 1,486 enrolled subjects, we found *Rickettsia(R) typhi in 102 (6.9%), Leptospira spp* in 44 (2.9%), Seoul virus in 2(0.1%), and *R felis* in 1 (0.07%) subjects. *R typhi* was observed at all sites, most prevalent in Surabaya (11.8% of all subjects) and least prevalent in Yogyakarta (3.6%). *Leptospira* was most frequent in Semarang (5.4%), least in Jakarta (1.9%), and no cases in Denpasar, Bali. Seoul virus was only observed in one subject from Jakarta and Surabaya. Subjects with *Rickettsia* and *Leptospira* infections presented with multiple organ involvement, whereas liver involvement was prominent in subjects with Seoul virus infections. Fatalities in *Rickettsia* and *Leptospira* infections were 6.8%, and 2.3%, respectively, while two Seoul virus cases survived. All *R typhi* and Seoul virus cases, and 57% of *Leptospira* cases were diagnosed as other diseases. These findings highlight the importance to develop appropriate diagnostic criteria, to enhance laboratory capacities, to improve clinical management, and to initiate public health intervention.

2003

USE OF AN INDUCIBLE EXPRESSION SYSTEM TO EVALUATE THE EFFECT OF MUTATIONS IN *PNCA* ON THE PYRAZINAMIDE SUSCEPTIBILITY IN *MYCOBACTERIUM TUBERCULOSIS*

Yudith Cauna Orocollo[1], Patricia Sheen Cortavarría[1], Robert Gilman[2], Mirko Zimic Peralta[1]

[1]Universidad Peruana Cayetano Heredia, Lima, Peru, [2]Johns Hopkins University, Baltimore, MD, United States

Tuberculosis (TB) is a bacterial infection caused by *Mycobacterium tuberculosis (MTB*). TB is in epidemiologic vigilance to global level. The TB patients may have active or latent TB. The treatment of TB includes drugs as pyrazinamide (PZA), which is effective against dormant MTB. Often, mutations in the *pncA* gene cause resistance to PZA. These mutations may promote the total or partial loss of the pyrazinamidase (PZAse) activity. Previously, we identified *MTB* isolates resistant to PZA with *pncA* mutation. Mutant PZAses that showed a variety of PZAse activity according to the mutation: D49N and H51R affected directly the metal-binding site and T135P is near to the active site, neither showed activity. D12A, F94L,

and K48T are close to the metal-binding site or active site and showed middle activity, but for K48T was high. G78C is far from the active site and showed high activity. We want to evaluate the effect of *pncA* mutations on the PZA susceptibility in a *pncA knockout MTB* strain (*pncA KO MTB*). The *pncA KO MTB* strain was complemented with the mutated *pncA* using an inducible expression system. The wild-type (WT) and mutant *pncAs* were cloned in pNIT. The recombinant plasmids were transformed into *E. coli* and then in *pncA KO MTB* strain by electroporation. The *pncA* expression was induced in the complemented-*pncA KO MTB* strains and the PZAse activity was measured using the Wayne colorimetric test. In addition, the PZA minimum inhibitory concentration (MIC) was estimated. The association between PZAse activity and PZA susceptibility will be evaluated by Spearman correlation. In our first results, the complemented-*pncA KO MTB* strains with WT and G78C *pncA* gene restored its PZAse activity, but the color intensity was more for WT *pncA* complemented strain than with G78C, and PZA MIC was at 100 ug/mL for both strains. Likewise, the complemented strain with D49N did not restore its PZAse activity and was highly PZA resistant (MIC: 1000 ug/mL). We have planned to evaluate the other complemented strains. The inducible expression system will allow us to determine the specific level of PZAse activity and susceptibility to PZA of each mutant *pncA* in *pncA KO MTB* strain.

2004

WILLINGNESS TO VACCINATE AGAINST INFLUENZA A (H1N1) PDM09 AMONG UNIVERSITY EMPLOYEES IN BRAZIL

Guilherme L. Werneck[1], Eduardo Faerstein[2]

[1]Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil, [2]Universidade do Estado do Rio de Janeiro, Rio de Janeiro, Brazil

In Brazil, a vaccination campaign against a new subtype of influenza A (H1N1) human virus of swine origin started in 2010 reaching almost 90 million people. Coverage among adults between 20 to 39 years of age reached 81%, varying from 63% to 91% across the Brazilian states. Why so many people did not get a widely available and free of charge vaccine during a severe outbreak being broadcasted in the news is intriguing. In 2012 we investigated, among university employees, factors associated with willingness to uptake pandemic influenza vaccination if a new campaign was to be carried out in the future. This is cross-sectional study among nonfaculty civil servants at university campi located in Rio de Janeiro, Brazil. The main outcome binary variable was "willingness to uptake a pandemic influenza vaccine in the future". Exposure variables were gender, age at the 2010 influenza epidemic, race, educational status, and occupation. Associations between variables were expressed as odds ratios (OR) with respective 95% confidence intervals (95%CI) estimated by logistic regression. Among the 2828 participants, 40.9% did not take the influenza A (H1N1)pdm09 vaccine and 15.9% would not be willing to take the vaccine in the future. Not willing to vaccinate was strongly associated with not taking previously the influenza A (H1N1) pdm09 vaccine (OR=11.6, 95%CI:8.77-15.4). Among those who had not taken the influenza vaccine, those aged >60 years and employed in non-health related occupations were significantly less willing to vaccinate in the future. For those who had previously taken the influenza vaccine, willingness to vaccinate was lower among females. Vaccine hesitancy is a recognized public health concern in developed countries but has not been considered as such in Brazil until recently when the recent outbreaks of yellow fever have shed light on the problem. Since a first experience of vaccination is strongly associated with willingness to vaccinate in the future, efforts should be made to identify population characteristics and their reasons to refuse vaccination and develop focused strategies to break the chain of vaccine hesitancy.

2005

DEMOGRAPHIC AND CLINICAL CHARACTERISTICS OF CHILDREN WITH INVASIVE PNEUMOCOCCAL DISEASE IN LIMA, PERU

Franco Castillo-Tokumori[1], Erik Mercado[1], Madhelli Marcelo[1], Olguita Del Aguila[2], Isabel Reyes[3], Francisco Campos[4], Maria Castillo[5], Andres Saenz[6], Eduardo Chaparro[7], Roger Hernandez[7], **Theresa Jean Ochoa**[8]

[1]Universidad Peruana Cayetano Heredia, Lima, Peru, [2]Hospital Nacional Edgardo Rebagliati Martins, Lima, Peru, [3]Hospital de Emergencias Pediatricas, Lima, Peru, [4]Hospital Nacional Docente Madre-Niño San Bartolome, Lima, Peru, [5]Instituto Nacional de Salud del Niño, Lima, Peru, [6]Hospital Daniel A. Carrion, Lima, Peru, [7]Hospital Cayetano Heredia, Lima, Peru, [8]University of Texas School of Public Health, Houston, TX, United States

Invasive pneumococcal disease (IPD) and vaccine serotypes have decreased since the introduction of pneumococcal conjugate vaccines (PCV). However, serotype 19A IPD is currently one of the most common causes of replacement disease after PCV7 and PCV10 introduction. In Peru, PCV10 was introduced into the childhood immunization schedule on 2011, and PCV13 on 2015. The aim of this report is to describe the demographic and clinical characteristics of children with IPD due to serotype 19A in Lima, Peru; to better understand the current trends. We are conducting a multicenter, passive surveillance study (Nov-2016 to Dec-2019) to determine the changes in serotypes and antimicrobial resistance in patients with IPD after PCV introduction in Lima. We are evaluating antibiotic susceptibility by E- test (penicillin and ceftriaxone) and by disc diffusion (azithromycin, clindamycin, and tetracycline). Strains are serotyped by a sequential multiplex PCR. As to date (Nov-2016 to Feb-2018), we have identified 45 S. pneumoniae isolates in children; 49% are serotype 19A (n=22), all isolated from children >1 year old; 7 isolated in children 1-2 years, 11 in children 2-5 years, and 4 in children >5 years. 19 children had pneumonia as the main diagnosis, 2 meningitis, and 1 peritonitis. The most common comorbidities were: asthma (n=2), malnutrition (n=2) and prematurity (n=2). Regarding vaccination status, 1 patient received PCV7, 8 received PCV10, 5 received either PCV10 or PCV13 (transition period), 4 received PCV13 (2 patients with complete 2+1 schedule), 2 had no PCV vaccination, and 2 have no data available. Both meningitis strains were resistant to penicillin and ceftriaxone. Among non-meningitis strains (n=20), penicillin resistance was 15%, azithromycin and tetracycline 100%, and clindamycin 95%. Current trends show serotype 19A as the main serotype circulating in Lima, associated with high resistance rates to commonly used antibiotics. This is and ongoing study; therefore, we will continue to monitor trends over time.

GENOTYPING AND DRUG RESISTANT PREVALENCE OF *MYCOBACTERIUM TUBERCULOSIS* IN SOUTHERN PENINSULA OF HAITI

Md Siddiqur Rahman Khan[1], Michael Lauzardo[2], Madsen Beau de Rochars[3], Chie Nakajima[4], Muhammad Manjurul Karim[5], John Glenn Morris, JR[6], Apichai Tuanyok[1]

[1]Emerging Pathogens Institute, Department of Infectious Diseases and Immunology, University of Florida, Gainesville, FL, United States, [2]Emerging Pathogens Institute, Southeastern National Tuberculosis Center, Department of Medicine, Division of Infectious Diseases and Global Medicine, University of Florida, Gainesville, FL, United States, [3]Emerging Pathogens Institute, College of Public Health and Health Professions, University of Florida, Gainesville, FL, United States, [4]Research Center for Zoonosis Control, Division of Bioresources, Hokkaido University, Sapporo, Japan, [5]University Dhaka, Dhaka, Bangladesh, [6]Emerging Pathogens

Institute, College of Medicine, University of Florida, Gainesville, FL, United States

Tuberculosis (TB) has been a major public health problem with 10.4 million of new TB cases with 1.3 million deaths in 2016. Haiti is one of the poorest countries in the Western Hemisphere with 16,431 of TB cases and a high incidence rate in 2015. A hospital based study was conducted in Haiti during 2014 and 2015. Sputum specimens obtained from 664 patients with suspected pulmonary TB were further tested by culture and fluorescent microscopy. Sixty-seven (10.1%) were smear positive and 119 (17.9%) were culture positive in liquid or solid media. Drug susceptibility tests were performed in randomly selected 102 isolates using solid media with isoniazid (INH; 0.2 µg/mL and 1.0 µg/mL) and rifampin (RIF; 1.0 µg/mL). Twenty (19.6%) were mono-resistant and 6 (5.9%) were multi drug resistant (MDR). Line probe assays, a molecular technique, were used to identify mutations in 81 base-pair of the Rifampicin Resistance Determining Region (RRDR) of *rpoB* gene for RIF resistance and *inhA* and *katG* gene for INH resistance. Seventy-five out of 119 isolates were tested. Eight (10.7%) isolates were mono-resistant and 4 (5.3%) strains were MDR. Two known mutation patterns, D513V and S531L, were identified in these resistance strains, while two strains had no known mutations in any of these genes. Sequence analysis of the RRDR in both strains showed that they had a novel amino acid substitution mutation S531G. Spoligotyping was conducted on 119 positive isolates. Of these, 31 known shared international types (SITs) were identified, while the other 32 spoligotypes were novel. Among these known SITs, the SIT2 (13.1%), SIT764 (11.1%) and SIT42 (7.4%) were the dominant. Phylogenetically, our study has identified that majority of the Haitian isolates are grouped with 3 major clades: H3 (24.7%), H2 (12.4%), and T1 (12.4%) which are also found in four broad geographic areas including Africa, the Americas, Europe, and Asia. This would suggest that the transmission of TB to Haiti was through the European colonization. Our study has shown that TB remains a public health problem in Haiti, and a better case management and pathogen characterization for the MDR-TB are greatly needed.

2007

COMPARISON OF TWO DECONTAMINATION METHODS OF SPUTUM SAMPLES FOR THE DIAGNOSIS OF TUBERCULOSIS BY MODS SYSTEM

Adrián J. Quintana Bedoya, Elisa D. Roncal Rios, Hector J. Arteaga Pillaca, Jorge Coronel Herrera, Mirko Zimic Peralta, Patricia Sheen Cortavarría

Universidad Peruana Cayetano Heredia, Lima, Peru

The early diagnosis of tuberculosis by microbiological methods, as well as the detection of susceptibility to drugs, have special importance in developing countries. In addition to conventional culture media based on eggs, the systems BACTEC MGIT® and MODS, based on liquid culture, are currently aviable but the contamination being a fundamental problem. The objective of this study is to compare two decontamination methods of sputum samples, based on the Petroff method, using a mixture of NaOH (0.5M), sodium citrate (0.65M) and N-acetyl-L-cysteine (NALC) (0.015M), in proportion 1:1 with the sputum sample for 15 minutes at room temperature. The standard method (A) store the mixture of NaOH and Sodium Citrate at 4°C and combine this mixture with the NALC the day of the process while the modified method (B) store the individual solutions (2X) and combine this and the NALC the same day of the process. MODS was the diagnostic methodology. PANTA ® was used as a suplement of Middlebrock 7H9 culture media. Clinical samples were used. The percentage of contamination issued with each method, based on the total of processes without conssidering repetitions, was calculated. The inverse of this was interpreted as a percentage of effectiveness. The result was that the "A" method showed an effectiveness of 62.5% (111/296) while the "B" method showed an effectiveness of 98% (5/255), using the MODS as diagnosis method. It is recommended the implementation of the method "B" of decontamination for TB diagnosis, using the MODS methodology, in hospitals and laboratories in developing countries for a cheaper and effective microbiological diagnosis of tuberculosis.

2008

SMS FOR PHARMACIES AS AN EDUCATIONAL TOOL TO IMPROVE THE KNOWLEDGE ON PREVENTION AND EARLY DETECTION OF MULTIDRUG-RESISTANT TUBERCULOSIS IN A DISTRICT OF LIMA, PERU

Jorge G. Hernandez-Cordova[1], Virgilio Failoc Rojas[2]

[1]Universidad Peruana Cayetano Heredia, Lima, Peru, [2]Pedro Ruiz Gallo University, Chiclayo, Peru

In spite of the slow decrease of Tuberculosis (TB) in the world, Peru still registers one of the highest figures of sensitive and MDR TB of the Americas. Widespread private pharmacies are the first point of contact for many symptomatic respiratory patients, pharmacy workers can play a role in early detection and referral of cases to the TB programs. To evaluate the change in the baseline level of knowledge that pharmacy workers have before an educational intervention based on the sending of SMS (Short Messages Service). A pre-intervention knowledge survey was conducted on a random sample of 63 pharmacies in Lima and Chiclayo Peru. Previously, a pilot survey was carried out to adapt the SMS, pre-testing and evaluation of their content validity. That helped to consider preferences such as using the acronym "TBC" in the SMS instead of openly using the stigma related word tuberculosis. Later for the intervention one participant for each pharmacy received 25 SMS. 63 respondents 76.2% were women, the average age was 27 CI: 19- 72 years. They reported that the most frequent symptom of tuberculosis was cough (92.1%) and the most useful diagnostic test was the sputum test (71.4%). The mean score of knowledge before the intervention was 11.6 ± 1.7 points out of 17, having 9 or more points was deemed as pass. Regarding knowledge about TB, 98.4% answered that TB is transmitted among people coughing, 49.2% answered that patients with tuberculosis can almost always be cured; 9.5% responded that patients with MDR-TB are those who show resistance to isoniazid and pyrazinamide, and 33.3% of the respondents answered that the consequence of incomplete treatment is resistant TB. Conclusions: Workers in private pharmacies have adequate knowledge with better results in TB prevention and diagnosis, important gaps persist in knowledge about treatment and MDR-TB. Most of participants reported acceptance with the SMS intervention. This study served as a baseline for the subsequent evaluation of the impact of the intervention.

2009

DETERMINATION OF RESISTANCE TO PYRAZINAMIDE BY QUANTITATIVE WAYNE FROM SPUTUM SAMPLES FROM PATIENTS WITH TUBERCULOSIS

Emily Toscano[1], Mirko Zimic[1], Adrian Quintana[1], Hector Arteaga[1], Katherine Vallejos[2], Ricardo Antiparra[1], Yudith Cauna[1], Eduardo Ticona[2], Luz Huaroto[2], Raquel Mugruza[2], Patricia Sheen[1]

[1]Universidad Peruana Cayetano Heredia, Lima, Peru, [2]Tuberculosis Working group, Lima, Peru

Tuberculosis (TB) is considered the ninth cause of death worldwide. The effort to eradicate it has made possible to reduce deaths in patient sensitive to drugs, however, the biggest problem remains the multidrug-resistant (MDR). In 2015, in Peru, 1,365 cases of MDR TB were recorded. Therefore, establishing truthful methods of diagnosis of resistance is important for the prompt and adequate treatment. The objective of this work is to determine the resistance to pyrazinamide (PZA), one of the first line drugs, which is converted to pyrazinoic acid (POA) by the bacteria. Diagnosis of PZA resistance, is not routinely performed in part due to subjectivity of the Wayne test and long periods of culture. MGIT tests were used to evaluate PZA resistance in sputum samples to reduce time to detection; although the efficiency was high, the uninterpretable results

was 41%. Preliminary results showed that the Direct Quantitative Wayne allows objective measurement of resistance to PZA, by quantifying POA produced by mycobacteria in samples of sputum culture supernatants. The samples (n= 146) were cultured in 7H9 medium for 7-10 days, then PZA was added and incubated for 3 days. Finally, 10% ferrous ammonium sulfate was added. The supernatant was used to measure optical densities by a spectrophotometer at 450nm. The concentrations of POA (µM), were calculated from a standard curve whose minimum concentration was 31.25 µM (O.D 0.0072±0.003) and maximum 4000 µM (O.D 0.5841±0.015) with an r^2= 0.9999. Preliminarily, these results were compared with values obtained from visual evaluation of the color, being 0 (resistant n=14), 1, 2 and 3 (intensities of sensitivity, n1=49, n2=59 y n3=24) to see if there was correspondence between the ODs and this values. The (0) samples had an average concentration of 65.63 ± 18.04 (SEM) µM of POA, the samples weakly positive (1) samples 234.3 ± 28.83 µM, the (2) samples 530.4 ± 80.06 µM and the (3) samples 1657 ± 235.6 µM, there were significant difference between groups (p<0.0001). Now we are evaluating the strains with gold standard (MGIT), we expect results that promises an inexpensive and automated assay to detect PZA resistance from sputum.

2010

EVALUATION OF THE ROLE OF MSMEG_0232 GENE IN THE EFFLUX OF PIRAZINOIC ACID IN MYCOBACTERIUM SMEGMATIS

Luz Saavedra, Ricardo Antiparra, Marco Santos, Mirko Zimic, Patricia Sheen

Universidad Peruana Cayetano Heredia, Lima, Peru

Tuberculosis (TB) is a disease caused by Mycobacterium tuberculosis (MTB), currently considered a global emergency by the World Health Organization (WHO), and that mostly affects the developing countries. Pyrazinamide (PZA), a first line drug against TB, is known for being capable of eliminating MTB in their non-replicating state. This drug plays a key role in shortening the duration of treatment against MTB and its inclusion is crucial in the treatment of patients infected with strains of multidrug-resistant MTB (MTB-MDR). Therefore, the growing occurrence of PZA resistant isolates is a serious threat to public health. In view of this problem, many efforts have been made to understand the mechanisms of resistance to this drug. One of the key findings has been to find that the presence of mutations in the pncA gene, which codes for pyrazinamidase and converts PZA to its active form, pyrazinoic acid (POA), is the main mechanism of resistance to PZA. These mutations are found in more than 90% of the clinical isolates resistant to PZA, but do not explain all cases of resistance in MTB. It has been suggested that the other cases could be explained by mutations at the level of the POA efflux pump. However, despite being of great relevance, the identity of this protein is not clear. Around this, recently an analysis of the proteome of MTB has identified 4 possible candidate genes and that have also been found to harbor non synonymous mutations in resistant strains. The present project therefore aims to evaluate the role of one of these candidate homologous genes in the strain naturally resistant to PZA Mycobacterium smegmatis (Msm). For this, a recombinant strain was generated with the CRISPR interference system (CRISPRi) for the orthologous gene Msm_0232. Subsequently, the level of transcriptional repression by RTqPCR and the efflux rate of POA was evaluated. Our results show that preliminarly, after the induction of the CRISPRi, there are no significant decreases in the POA efflux rate. Thus, if confirmed, Msmeg_0232 would be discarded as a POA efflux pump in Msm.

2011

HIGH PREVALENCE OF RESPIRATORY VIRUS AND ATYPICAL BACTERIUM AMONG CHILDREN WITH A PROBABLE DIAGNOSIS OF PERTUSSIS

Jorge Valverde[1], Stephanie Saiki[1], Angela I. Cornejo-Tapia[1], Maria E. Castillo[2], Miguel A. Aguilar-Luis[3], Fernando Vásquez-Achaya[1], Wilmer G. Silva-caso[1], Olguita del Aguila[4], Carlos Bada[5], Erico Cieza-Mora[6], **Juana M. del Valle-Mendoza**[7]

[1]Universidad Peruana de Ciencias Aplicadas, Lima, Peru, [2]Instituto Nacional de Salud del Niño, Lima, Peru, [3]Universidad Peruana de Ciencias Aplicadas, Instituto de Investigación Nutricional, Instituto de Investigación de Enfermedades Infecciosas, Lima, Peru, [4]Hospital de Emergencias Pediátricas, Lima, Peru, [5]Hospital Edgardo Rebagliati Martins, Lima, Peru, [6]Hospita Regional Docente de Cajamarca, Cajamarca, Peru, [7]Universidad Peruana de Ciencias Aplicadas, Instituto de Investigación Nutricional, Lima, Peru

Acute respiratory infections (ARIs) as the most common cause of morbidity and mortality in children, remains a major concern, especially affecting children under 5 years old from low-income countries. Unfortunately, information regarding their epidemiology is still limited in Peru. A secondary data analysis was performed from a previous cross-sectional study conducted in children with a probable diagnosis of Pertussis from January 2010 to July 2012. All samples were analyzed via PCR for the following etiologies: Influenza-A, Influenza-B, RSV-A, RSV-B, Adenovirus, Parainfluenza 1 virus, Parainfluenza 2 virus, Parainfluenza 3 virus, Mycoplasma pneumoniae and Chlamydia pneumoniae. A total of 288 patients were included. The most common pathogen isolated was Adenovirus (49%), followed by Bordetella Pertussis (41%) from our previous investigation, Mycoplasma pneumonia (26%) and Influenza-B (19.8%). Coinfections were reported in 53.5% of samples and the M. pneumoniae and Adenovirus (9%) was the most common association. There was a high prevalence of Adenovirus, Mycoplasma pneumoniae and other etiologies in patients with a probable diagnosis of pertussis. Despite the presence of whooping and other clinical characteristics highly suspicious of pertussis, secondary etiologies should be considered in children under 5 years-old in order to give a proper treatment.

2012

BORDETELLA PERTUSSIS IN CHILDREN HOSPITALIZED WITH A RESPIRATORY INFECTION. CLINICAL CHARACTERISTICS AND PATHOGEN DETECTION IN HOUSEHOLD CONTACTS

Juana M. del Valle-Mendoza[1], Wilmer Silva-Caso[1], Miguel A. Aguilar-Luis[1], Cristina del Valle-Vargas[2], Erico Cieza-Mora[3], Andrea Silva[4], Johanna Martin-Luna[5], Ronald Aquino-Ortega[1], Jorge Bazán-Mayra[6], Pablo Weilg[5]

[1]Universidad Peruana de Ciencias Aplicadas, Instituto de Investigación Nutricional, Lima, Peru, [2]Univesidad de Barcelona, Barcelona, Spain, [3]Hospital Docente Regional de Salud de Cajamarca, Lima, Peru, [4]Instituto de Investigación Nutricional (IIN), Lima, Peru, [5]Universidad Peruana de Ciencias Aplicadas, Lima, Peru, [6]Dirección Regional de Salud de Cajamarca (DIRESA), Lima, Peru

Latin America is experiencing a resurgence of *B. Pertussis* infections affecting primarily infants under 6 months old. In Peru, the number of Pertussis cases doubled by the first half of 2017 compared to the previous year. In addition, limited laboratory resources in the rural setting represent an impediment to establishing the diagnosis in this vulnerable population. Methods: A consecutive cross-sectional study was conducted in Cajamarca, Peru from April 2016 to September 2017. A total of 88 children under 5 years old admitted with clinical diagnoses of 'whooping cough' were tested via polymerase chain reaction (PCR) for detection of *B. Pertussis*. Household contacts with respiratory symptoms were also analyzed for *B. Pertussis*. Results: A positive PCR result for *B. Pertussis* was observed in 20.5% of our samples (18/88), one-third of them were

from infants between 2 - 3 months old. The most common symptoms were paroxysms of coughing (88.9%), difficulty breathing (72.2%), cyanosis (77.8%) and fever (50%). The mother was the most common symptomatic carrier (27.8%), followed by uncles/ aunts (22.2%) among children with Pertussis. Conclusions: *B. Pertussis* is an important cause of respiratory tract infection in children under 5 years, primarily affecting infants to young to be immunized in whom the diagnosis is not always suspected. In rural areas of Peru, limited laboratory resources may be responsible for Pertussis underdiagnoses and increased antibiotics prescriptions.

2013

MECHANISM OF POST-DISCHARGE DEATH AND "SECOND HIT" INFECTIONS: THE EFFECT OF INTESTINAL INFECTIONS ON LUNG IMMUNITY

Shubhanshi Trivedi, Daniel T. Leung

The University of Utah, Salt Lake City, UT, United States

Up to 15% of children die during the first 6 months after hospital discharge in resource-limited settings, often exceeding in-hospital mortality. Verbal autopsy studies have shown that deaths are often preceded by new symptoms of cough or fever, suggesting that "second hit" respiratory infections may be major contributors. However, the mechanisms behind "second hit" infections remain unclear. Using a mouse model of intestinal infection by *Salmonella enterica* serovar Typhimurium (*S*. Typhimurium), we investigated how infection in the gut compartment can modulate immunity in the lungs. We first orally infected mice with a relatively low dose of *S*. Typhimurium (10^4 cfu) by gavage and six day's post infection we harvested lungs and assessed for antigen presenting cells (APCs) and innate lymphocytes by flow cytometry. We found higher percentage of plasmacytoid dendritic cells (pDCs), gamma-delta T cells and lower frequencies of monocytic dendritic cells (moDCs) in lungs of *S*. Typhimurium infected mice compared to uninfected mice. Furthermore, on subsequent challenge with *Klebsiella pneumoniae* we found that mice with prior intestinal infection responded with lower percentage of pDCs, moDCs and gamma-delta T cells, compared to mice without prior intestinal infection. Together these results suggest that *S*. Typhimurium infection in the gut effects lung innate lymphocyte and APC responses, potentially resulting in increased susceptibility to *K. pneumonia*e. At time of conference presentation, we will have complete data on survival and bacterial outcomes of mice receiving "second-hit" *K. pneumoniae* infections. In conclusion, this study reveals potential mechanisms of crosstalk between the lung and the gut during enteric infection that may affect susceptibility to subsequent respiratory infection. Our findings have the potential to uncover novel therapeutic strategies targeting the gut-lung axis during intestinal infections.

2014

TRANSCRIPTIONAL RESPONSES OF THE VECTOR SNAIL *BIOMPHALARIA GLABRATA* TO *SCHISTOSOMA MANSONI* AND TWO ADDITIONAL RELEVANT PARASITES: A COMPARATIVE APPROACH TO UNDERSTANDING SNAIL IMMUNITY

Lijun Lu[1], Lijing Bu[1], Si-Ming Zhang[1], Sarah K. Buddenborg[2], Eric S. Loker[1]

[1]*The University of New Mexico, Albuquerque, NM, United States,* [2]*Wellcome Sanger Institute, Hinxton, United Kingdom*

Biomphalaria glabrata is an important Neotropical snail vector of human schistosomiasis, a neglected tropical disease afflicting 206.5 million people. As part of an ongoing effort to characterize and eventually exploit the immune system of the snail for schistosomiasis control, this research aimed to reveal the full extent of the transcriptional response of *B. glabrata* when exposed to *Schistosoma mansoni* or to two other unrelated parasites it might readily encounter in nature, the echinostome fluke *Echinostoma paraensei* and the snail-infecting nematode *Daubaylia potomaca*. From this, we can identify common or unique features in the *B. glabrata* response to different parasites. M-line strain snails were individually exposed to each parasite and at 2, 8 and 40 days post exposure (dpe), 7-8 snails/group were collected. Unexposed control snails (matched at 2 and 40 dpe) were also sampled. Snails were extracted for RNA, PCR assays run to check for parasite presence, and cDNA libraries (3 snails/ group/time point) were paired-end sequenced on an Illumina NextSeq500 instrument. The published *B. glabrata* genome was used as a reference for mapping with STAR. Bioinformatics tools were used for differential expression (DE) gene analysis and Gene Ontology (GO) term enrichment analysis. On average, 12 million raw reads/snail were sequenced. Each parasite provoked a distinctive overall pattern of responses at all time points, but in general the responses provoked by the two trematodes, the sporocyst-producing *S. mansoni* and rediae-producing *E. paraensei* were more similar to each other (persistent patterns of overall down-regulation) than what was noted with the nematode (early down-regulation followed by dramatic late up-regulation). The results are consistent with the need for trematodes to establish stable long-term infections in which progeny are continually produced, relative to the nematode which overwhelms the snails and is transmitted only when the snail is about to die. The snail genes responsive in common to all three parasites, and those expressed in a parasite-specific way will be discussed and quantified in the current research.

2015

DIFFERENTIAL GENE EXPRESSION OF PIWI IN *BIOMPHALARIA GLABRATA* SNAILS WITH VARYING SUSCEPTIBILITY TO *SCHISTOSOMA MANSONI*

Andrea P. Borns[1], Carolyn Cousin[1], Freddie Dixon[1], Matty Knight[2]

[1]*University of the District of Columbia, Washington, DC, United States,* [2]*University of the District of Columbia & George Washington University, Washington, DC, United States*

B. glabrata is an important intermediate host for the human parasite *S. mansoni*. The Piwi (P-element induced wimpy testis in *Drosophila*) family of proteins maintains the integrity of the genome by silencing transposable elements in germ cells by interacting with small non-coding piRNAs. It acts as guardians of the genome, protecting it from harmful mutations. Under conditions of stress and other cellular perturbations, piwi in combination with heat shock protein Hsp90 and the Heat Shock Organizing Protein (HOP) are involved in canalization, a process that maintains the phenotype in the face of genotypic variation. This buffering system is conserved allowing organisms to adapt to stressful conditions. We hypothesized that piwi, HOP, and Hsp90 are expressed in a fashion that maintains the regulation of the *B. glabrata* endogenous retrotransposable element during parasite infection. To test this hypothesis, expression of transcripts encoding piwi and HOP were examined in juvenile resistant (BS90) and susceptible (BB02) snails to *S. mansoni* infection by real-time qPCR after exposure to miracidia. Results showed that during early infection of resistant BS90 snails, the transcript encoding piwi was upregulated post- exposure unlike in susceptible BB02 snail where the piwi transcript was downregulated in the same time frame post-exposure. Expression of the transcript encoding HOP was conversely upregulated within 30min after infection in susceptible but not in similarly exposed resistant snails. The expression of transcripts encoding *nimbus* reverse transcriptase and Hsp90 have previously been examined and was found to be upregulated only in early infected susceptible snails. Previous data suggest that the early upregulation of transcripts encoding HOP and Hsp90 in the infected susceptible snail, and downregulation of piwi in early-infected susceptible snails, results in less canalization that leads to a more stressful environment for schistosomes to survive and develop. On the other hand, resistant snails, consistently showing elevated piwi expression after infection are better canalized to ward off infection.

2016

TRANSCRIPTS ENCODING HUMAN SIGLEC HOMOLOGS IN *BIOMPHALARIA GLABRATA* SNAILS ARE REGULATED IN RESPONSE TO *SCHISTOSOMA MANSON*I INFECTION: A MODEL SYSTEM TO STUDY EVASION OF INNATE IMMUNITY IN CANCER

Olyemi G. Akinyele

University of the District of Columbia, Washington, DC, United States

Siglecs are sialic acid-binding, immunoglobulin-like lectins that attach to glycans on cell surfaces. They are important in immune cell signaling and are part of an organism's innate immunity. When the miracidia of *Schistosoma mansoni* infect freshwater snail, *Biomphalaria glabrata*, stress proteins are elevated. This deploys an immune response that upregulates the expression of various siglec homologs. The developing miracidia (sporocysts) evade lysis by disguising themselves as glycan structures that are similar to those found on their host's immune cell surface, which binds to the host siglecs, providing effective mimicry to prevent attack from the snail innate defense system. This evasive mechanism utilized by schistosomes to escape recognition and destruction in the snail host is remarkably similar to cancer cells that disguise themselves from the body's innate immune system, and are consequently, capable of surviving in a hostile environment. To determine the mechanism(s) that snails use, like cancer cells, to escape the innate immune response, we hypothesized that blocking siglecs homologs by RNA interference (RNAi) will prevent schistosomiasis in snails which mirrors the effect of blocking siglecs on several cancer cells. To test this hypothesis, we identified several human siglec homologs such as nuclear receptor, peroxidasin, and C1q by interrogating the *B. glabrata* genome, and examined the temporal regulation of their expression by real-time qPCR. Results showed that after early infection of susceptible *B. glabrata*, the siglec homologs were upregulated following parasite infection. Double-stranded RNA will be synthesized by *in vitro* transcription to knockdown the corresponding siglec transcript by transfection of newly infected snails. Blocking transmission of schistosomiasis by this approach will offer proof of principle that the same process can be used to interfere with cancer since they utilize same evasion pathway as *S. mansoni* in infected snails. Both schistosomes and cancer camouflage themselves by using siglec ligands to bind host siglecs, to prevent recognition and destruction by the host immune system.

2017

EXPLORING THE ROLES OF SMJNK AND SMP38 IN *SCHISTOSOMA MANSONI* AND ITS POTENTIAL AS THERAPEUTIC TARGETS AGAINST SCHISTOSOMIASIS

Sandra Grossi Gava[1], Naiara Clemente Tavares[1], Izabella Cristina Batista[1], Karina Barbosa Queiroz[2], Lodewijk Dekker[3], Franco Harald Falcone[3], Guilherme Oliveira[4], Marina Moraes Mourão[1]

[1]René Rachou Institute, Belo Horizonte, Brazil, [2]Universidade Federal de Ouro Preto, Ouro Preto, Brazil, [3]University of Nottingham, Nottingham, United Kingdom, [4]Vale Institute of Technology, Belém, Brazil

MAPKs are involved in *S. mansoni* development, reproduction and/or survival; and have been considered potential therapeutic targets. Due to the availability of a single treatment for schistosomiasis, this work aims at identifying drug targets, in which SmJNK and Smp38 are candidates themselves or specific parasitic genes regulated by them. First, we performed SmJNK and Smp38 knockdown in schistosomula by RNAi and assessed their transcriptional profile through RNASeq. Differentially expressed genes (DEGs) were identified by comparing each MAPK knockdown against untreated parasites. We identified 606 and 1154 DEGs in SmJNK and Smp38 knockdown schistosomula, respectively. A considerable proportion of DEGs (505) encodes proteins with unknown function and there is a significant crosstalk between both pathways. The SmJNK and Smp38 knockdown promotes decrease in gene expression related to antioxidant defense, structural composition of ribosomes, spliceosomes, cytoskeleton and purine metabolism pathway. Also, SmJNK and Smp38 knockdown was performed in adult worms, resulting in ~65% reduction in transcription levels. After knockdown, there was up to 86% reduction in oviposition in both treatments. As for SmJNK, oviposition was interrupted in the 6th day. Using the WormAssay software, knockdown male parasites for SmJNK presented an 80% movement reduction in the 8th day. To search for specific compounds, the structure of SmJNK is to be solved by crystallography. Thus, the synthetic SmJNK gene was cloned into the pCold-GST vector for recombinant protein production and expressed in *Escherichia coli*. The recombinant protein was obtained with the expected size and sequence was confirmed by mass spectrometry. A protein activity assay based on the interrogation of the ATP binding site using BODIPYFL ATP-γ-S fluorescent nucleotide which detects polarization was validated to test the activity of expressed protein. Evaluation of recombinant SmJNK activity is underway for further directed compound screening *in vitro*. This work allowed a better understanding of MAPKs signaling pathways, elucidating functional roles and targets they regulate.

2018

STUDY OF CHANGES IN THE TRANSCRIPTOME OF MOUSE BLADDER FOLLOWING BLADDER WALL INJECTION OF *SCHISTOSOMA HAEMATOBIUM* EGGS

Kenji Ishida, Evaristus Mbanefo, Loc Le, Michael Hsieh

Biomedical Research Institute, Rockville, MD, United States

Background: Infection with *Schistosoma haematobium* leads to urogenital schistosomiasis (UGS), which afflicts over 100 million people. UGS can cause hematuria, calcification of the bladder, and increased risk of secondary infections by bacteria or viruses, and it is also linked to bladder cancer. Previous studies have used a mouse model that involves injection of *S. haematobium* eggs into the bladder wall to examine the effect of parasite eggs on host bladder biology, and they have identified changes in genome-wide methylation, as well as changes in the transcript level of some genes by microarray analysis. Here, we perform RNA-Seq on egg injected bladders to expand the detection of changes in gene transcript level to the scale of the whole transcriptome. Methods: We followed a combined infection/injection animal model in which female BALB/c mice were infected with *S. haematobium* cercariae and then, after 5 weeks, administered either parasite eggs or hamster liver extract by bladder wall injection. Another group of control mice did not receive surgery. RNA-Seq was performed on the RNA isolated from the bladders 4 days after bladder wall injection. Results/Conclusions: RNA-Seq analysis of egg-injected bladders and controls will reveal host gene pathways activated by the presence of S. haematobium eggs. Of particular interest are urothelial cell-related genes, including cancer pathways, differentially expressed genes associated with infiltrating and resident leukocytes, and fibrosis-related gene pathways. RNA-Seq analysis of schistosome-specific genes highlight the challenges of performing the parasite side of dual RNA-Seq in the setting of low amounts of parasite RNA relative to host RNA.

USE OF THE *BIOMPHALARIA GLABRATA*, *SCHISTOSOMA MANSONI* HOST- PATHOGEN MODEL SYSTEM AS SURROGATE TO STUDY METASTATIC CANCER AS A PARASITIC DISEASE

Swara B. Yadav

University of the District of Columbia, Washington, DC, United States

Schistosoma mansoni is a parasite that causes the disease schistosomiasis in over 75 tropical and sub-tropical countries. In the lifecycle, human beings are the definitive host for parasites that sexually reproduce eggs that when released from human excreta into freshwater hatch to release the miracidia that infect the snail, *Biomphalaria glabrata.* By penetrating the head foot, migrate to the hepatopancreas, asexually

reproduce cercariae that infect human host where cercariae transform into schistosomula and develop into adult worms which survive many years in vasculature and avoid immune attack. Likewise, cancer develops without immune attack in host. Schistosomes mimic behavior of metastatic cancer by migrating to specific tissues. It shares another hallmark of cancer, there is no super-infection, a condition called as concomitant immunity. Due to these similarities in cancer and schistosomiasis, we hypothesize-metastatic cancer is a parasitic disease, hence molecular determinants that underscore metastatic cancer will also play a role in biology of parasitism. To test this, we examined expression of snail homologs of cancer related transcripts, E-cadherin, beta-Integrin, myc, p53 and Snail after early (0,30min,1hr,2hr,4hr,16hr) stages of *S.mansoni* infection of resistant or susceptible *B.glabrata* snails. Results show expression of matrix proteins E-cadherin and beta-integrin, as in cancer, downregulated upon early *S.mansoni* infection in *B.glabrata* susceptible but not resistant snails. Cells lose their adhering capacity and become free due to downregulation of these proteins.The extracellular matrix detaches due to contact-inhibition and transitions into motile mesenchymal cells that enter the bloodstream and other tissues-hallmark of metastatic cancer. Matrix protein downregulation is an important factor for Epithelial-Mesenchymal Transition. Ability to track signaling networks that control expression of homologs of cancer related transcripts in a snail responding to the parasite provides a convenient surrogate model system to identify pathways that can be blocked to treat both cancer and schistosomiasis.

COMPARISON OF METHODS FOR EVALUATING THE MOTILITY, INFECTIVITY AND VIABILITY OF SCHISTOSOME *CERCARIAE* IN WATER

Laura Braun[1], Lucinda Hazell[1], Fiona Allan[2], Aidan M. Emery[2], Michael R. Templeton[1]

[1]Imperial College London, London, United Kingdom, [2]Natural History Museum, London, United Kingdom

Schistosome cercariae are the human-infectious stage of the Schistosoma parasite. They are shed by intermediate host snails living in freshwater, and penetrate the human host's skin to develop into schistosomes, resulting in schistosomiasis infection. One way of cutting disease transmission is through water treatment, which aims to kill the cercariae to provide safe water for people to use as an alternative to infested lakes or rivers. At present, there is no standard method for assessing the impact of water treatment process on cercariae or definition of the point at which water is considered safe. Instead, water treatment studies to-date have assessed one of three cercarial characteristics: motility (ability to move), infectivity (ability to penetrate host skin) or viability (ability to penetrate host skin and develop into schistosomes). Motility is assessed microscopically, and assumes that cercariae are dead when they stop moving. Infectivity is assessed by counting cercariae before and after being exposed to a skin sample, the difference assumed to have penetrated the skin. Viability tests often use animal testing to determine if cercariae develop into worms. Vital and non-vital dyes have also been used to stain cercariae. The accuracy of these methods is uncertain and significant sources of error have been identified. We evaluated the relationship between five commonly used methods - movement, skin attachment, Fluorescein Diacetate, Hoechst, and neutral red dye - using *S. mansoni* cercariae. This research crucially establishes which methods most accurately determine the point at which water can be considered safe from a schistosome cercaria standpoint, thereby defining standards for confirming the effectiveness of water treatment processes (e.g. using chlorination or filtration) both in field sampling and laboratory trials. This work is timely as we look towards elimination of schistosomiasis as a public health concern and the role of water treatment in integrated interventions alongside preventive chemotherapy.

DETECTION OF *SCHISTOSOMA MANSONI* SPOROCYST STAGE IN *BIOMPHALARIA GLABRATA* MOLLUSK IN EXPERIMENTAL CONDITIONS

Márcia Oliveira Casotti[1], Roseli Tuan[2], Michele Gomes[1], Expedito José Albuquerque Luna[3], Emmanuel Dias-Neto[1], Fabiana Martins Paula[1], João Renato Rebello Pinho[1], Flair José Carrilho[1], Ronaldo Cesar Borges Gryschek[1], Maria Cristina C. Espírito-Santo[1]

[1]Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil, [2]Superintendência de Controle de Endemias (SUCEN), São Paulo, Brazil, [3]Instituto de Medicina Tropical-Faculdade de Medicina/Universidade de São Paulo/Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil

Approximately 240 million people in the world are infected by the *Schistosoma mansoni.* In Brazil, the goal of the control program for this parasitosis is to reduce the risk of its geographic expansion. The main intermediate host of *Schistosoma mansoni* is *Biomphalaria glabrata.* The detection of larval stages of the parasite in intermediate hosts is an important challenge to public health. The objective of this study is to standardize the detection of *Schistosoma mansoni* as primary sporocysts developing in *B. glabrata* mollusks artificially infected with Belo Horizonte (BH) *Schistosoma mansoni* strain, using the Polymerase Chain Reaction (PCR) and Two Sequential PCR-amplification (Re-PCR). From a laboratory cycle of *S. mansoni* we obtained thirty miracidea. Twenty mollusks *B. glabrata* specie were infected, four sporocysts packages were dissected, and the head-foot part was removed, and tissues were used the DNA extraction using the DNAeasy Tissue Kit (Qiagen). DNA was quantified in Nanodrop and two molecular approaches were compared, cPCR and Re-PCR. DNA samples were amplified using primers targeting a tandem repeat sequence of 121pb and amplification products were evaluated in 2% agarose gels. The amplification products showed distinct profiles when comparing the different DNA sources. For the head-foot tissues, clear bands were visible for both cPCR and Re-PCR suggesting a lower concentration of PCR inhibitors. The *S. mansoni* sporocyst molecular detection from the head-foot part demonstrated a high sensitivity in early characterization of snails infection to *S. mansoni* in experimental conditions and so can represent a tool in schistosomiasis monitoring and control.

2022

CYTOKINES AS PREDICTORS OF *SCHISTOSOMA MANSONI* INFECTION INTENSITIES AND REINFECTION RATES

Rachel Francoeur[1], Aaron Atuhaire[2], Moses Arinaitwe[2], Nankasi Andrina[2], Aidah Womboko[2], Fred Besigye[2], Candia Rowel[2], Poppy H. Lamberton[1]

[1]University of Glasgow, Glasgow, United Kingdom, [2]Ugandan Ministry of Health, Kampala, Uganda

Schistosomiasis is a commonly occurring neglected tropical disease with over 240 million people infected globally. Despite over a decade of mass drug administration (MDA) in Uganda, certain endemic hotspots continue to persist whereby infection intensities and prevalence are similar to those recorded before MDA was rolled out. Past studies show a potential association with various cytokines and reduction in reinfection rates post chemotherapeutic treatment. This study investigates changes in cytokine profiles post treatment in order to determine potential predictors of resistance to *Schistosoma mansoni* infections. Samples were obtained from 197 school children aged 6-14 in the Mayuge district of Uganda. Infection data was acquired using three days of duplicate Kato-Katz to obtain *S. mansoni* egg counts. Soil-transmitted helminth (STH) egg counts and urine for point-of-care circulating cathodic antigen tests (POC-CCA) for *S. mansoni were also obtained*. Finger prick blood samples were obtained at baseline, 24 hours, 3 weeks, 9 weeks, and 6 months post treatment with praziquantel for immunological analysis and stored on filter paper. Using a commercial fluorescent bead-based Luminex cytokine assay, cytokine

profiles were established at each time point and correlated with infection data. Potential cytokine predictors of resistance-to-reinfections as well as any differences between those with high and low infection intensities of *S. mansoni* will be presented. These results will contribute to a broader biostatistical study looking at host factors that influence *S. mansoni* clearance and reinfection rates. Implications will be discussed in relation to ongoing MDA programmes and how to maximise treatment success in individuals taking the drugs.

PROTEOMIC ANALYSIS AND IDENTIFICATION OF *SCHISTOSOMA MANSONI* CERCARIAL TAIL PROTEINS

Sreemoyee Acharya, Gunnar R. Mair, Michael J. Kimber, Timothy A. Day

Iowa State University, Ames, IA, United States

Schistosomiasis, caused by *Schistosoma mansoni*, is responsible for infecting 200 million patients worldwide; it is a key neglected tropical parasitic disease. An infection is initiated when the cercariae is released from its intermediary host, a *Biomphalaria* snail, into the surrounding water. Cercariae are free swimming, highly motile forms with bifurcated tails and they penetrate the mammalian skin tail-first, thus infecting the human host. Post attachment, the cercariae sheds its tail and the resulting somule continues to develop inside the host circulatory system. Cercarial tail motility plays an essential role in host location and survival of the parasites outside the mammalian body, yet the proteins supporting this prolonged, vigorous movement are not understood. In this study, we have extracted and identified the proteins in the isolated cercarial tails. Using mechanical separation of tails and bodies and mass spectrometric analyses, we have identified a total of 945 proteins in the combined cercarial proteome from 4 independent samples: 791 proteins in the cercarial tails and 645 proteins from the somule bodies. Based on the results and the research conducted from the *Schistosoma mansoni* database, we have selected 12 proteins upregulated in cercarial tails for recombinant expression allowing for biochemical studies and antibody production to localize these uncharacterized schistosome proteins. These include: twitchin, glycogenin, glutamine synthetase, tegument-allergen like protein; taurocyamine kinase, lengsin and 3 hypothetical proteins. By determining the function and localization of these specific proteins in the cercariae, we hope to propose possible therapeutic mechanisms via which parasitic host skin invasion can be avoided.

COMPARATIVE GENOMICS PROVIDES INSIGHT INTO THE EVOLUTION OF TREMATODES IN THE FAMILY *FASCIOLIDAE*

Young-Jun Choi[1], Peter U. Fischer[1], Thanh Hoa Le[2], David Blair[3], Paul J. Brindley[4], Jose F. Tort[5], Miguel M. Cabada[6], Makedonka Mitreva[1]

[1]Washington University School of Medicine, St. Louis, MO, United States, [2]Vietnam Academy of Science and Technology, Hanoi, Vietnam, [3]James Cook University, Townsville, Australia, [4]George Washington University School of Medicine and Health Sciences, Washington, DC, United States, [5]Universidad de la República, Montevideo, Uruguay, [6]University of Texas Medical Branch, Galveston, TX, United States

The liver and intestinal flukes in the family Fasciolidae cause zoonotic food-borne infections that impact both agriculture and human health throughout the world. Here, we present a whole genome sequence-based comparative analysis of *Fasciola hepatica* (1.14 Gb), *Fasciola gigantica* (1.13 Gb), and *Fasciolopsis buski* (748 Mb) with the aim to better understand their evolutionary history and the genetic basis underlying their phenotypic and ecological divergence. The split between the genera *Fasciolopsis* and *Fasciola* took place around 90 Ma in the late Cretaceous period, and between 65 and 50 Ma an intermediate host switch and a shift from intestinal to hepatic habitats occurred in the *Fasciola* lineage. The rapid climatic and ecological changes during this period (e.g., K–Pg mass extinction and Paleocene–Eocene Thermal Maximum) may have contributed to the adaptive radiation of these flukes. Analysis of gene family dynamics indicates the expansion of cathepsins, fatty acid binding proteins, protein disulfide-isomerases and molecular chaperones in *Fasciola* spp. highlighting the significance of excretory-secretory proteins in lineage-specific adaptation. *F. hepatica* and *F. gigantica* diverged around 5 Ma near the Miocene-Pliocene boundary that coincides with a reduced faunal exchange between Africa and Eurasia. Estimates of historical *F. hepatica* population size indicate a severe decrease in the effective population size around ~10 Ka, consistent with its recent global spread associated with ruminant domestication. Genome-wide analysis of selection signatures reveals that G-protein-coupled receptors are under positive and/or relaxed purifying selection in *Fasciola*, suggesting their roles in adaptation of physiology and behavior to new ecological niches. Together, these findings deepen current understanding of the biology and evolution of these important but neglected pathogens, and the genomic resources provided by these studies will help support the development of improved interventions, and lay a solid foundation for genomic epidemiology to trace potential drug resistance or introduction of infection.

EXPRESSION OF EMBRYONIC SOXB IN SCHISTOSOMES AFTER HOST INVASION

Stephanie Wood[1], Kenji Ishida[2], James Hagerty[1], Anida Karahodza[1], Janay Jones[3], Emmitt R. Jolly[1]

[1]Case Western Reserve University, Cleveland, OH, United States, [2]Biomedical Research Institute, Rockville, MD, United States, [3]Wilkes Community College, Wilkesboro, NC, United States

Schistosome helminths are a major global problem and infect over 200 million people. Human infection occurs when transient and free-swimming schistosome larvae, cercariae, penetrate human skin and begin a complex developmental transition in which the larvae adapt from a freshwater environment to survival in saline blood. As the parasite develops in the host it expands its the primordial gut, develops the tegumental surface, elongates its body, and evades the host immune response. While we have made significant progress in our understanding of schistosome biology, we are still limited when it comes to defining some of the basic genetic pathways crucial for schistosome development after infection of the human host. Sox B proteins are transcriptional activators expressed prior to blastulation in mammals and necessary for embryogenesis. Sox B proteins are pioneering transcriptional activators that coordinates with several protein partners and is associated with pluripotency and stem cells, neuronal differentiation, gut development, and cancer. Here we describe a schistosome Sox B homolog. Although most mammalian studies on Sox proteins have been analyzed in cell culture, schistosomes express a Sox2-like gene after infecting a mammalian host, long after formation of a blastula, when schistosomes have about 1000 cells. We have characterized a schistosome SOXB (SM-SOXB) homolog whose transcript is developmentally regulated, and we show that it is indeed a conserved Sox protein. SM-SOXB functions as a transcriptional activator, and it binds SOX specific DNA elements. We show its localization in the cercariae and developing schistosomula. However, it is not clear that the schistosome SOXB functions in conjunction with some known coregulators of SoxB proteins, suggesting that it may play a distinct role or have a differing mechanism of action in developing schistosomes. This work demonstrates that schistosomes are an unexpected resource to expand a potential role for Sox2 function at the organismal level, rather than at the embryonic level.

2026

THE "GESHIARO" PROJECT PROTOCOL: DEVELOPING A SCALABLE AND COST-EFFECTIVE MODEL OF INTERVENTIONS FOR THE INTERRUPTION OF TRANSMISSION OF SOIL-TRANSMITTED HELMINTHS AND SCHISTOSOMIASIS IN ETHIOPIA

Anna E. Phillips

Imperial College, London, United Kingdom

National deworming programmes rely almost exclusively on the mass administration of deworming drugs to children to control morbidity caused by these parasitic infections. The provision of other interventions, such as water, hygiene and sanitation behaviour change, and expansion of drug coverage to treat the entire at-risk population—not just children—should allow disease reductions achieved through drug distribution to be sustained once transmission has been interrupted. Experience indicates that the transmission of some parasitic worms can be broken in some settings through provision of multiple interventions, but it has not been attempted at scale in a developing country through the existing health system. The Geshiaro project has the potential to define an 'End Game' for soil-transmitted helminths (STH) and schistosomiasis (SCH) programmes. Interrupting transmission of these infections would eliminate the need for long-term repeated mass drug administration, lead to sustained health improvements in children, and allow health systems to focus on other disease priorities. The investment will test the feasibility of interrupting transmission at a large scale within a health system, through mass drug administration as well as complementary Water, Sanitation and Hygiene (WaSH) Interventions to sustain disease reductions and develop a working model for scaling up transmission interruption in Ethiopia and other countries. Interrupting transmission will require four years of biannual treatment to drive disease prevalence below 2%, the threshold at which transmission is believed to be no longer possible (transmission interruption). At that point, the WaSH interventions will be fully scaled up to sustain reductions, and treatment can stop. Five years will be needed to accomplish these implementation components and drive prevalence down to levels that cannot sustain transmission.

QUANTITATIVE BIAS ANALYSIS TO ACCOUNT FOR MISCLASSIFIED PEDIATRIC DIARRHEA IN A CLUSTER-RANDOMIZED WATER INTERVENTION TRIAL

Kristen Aiemjoy[1], Solomon Aragie[2], Sintayehu Gebresillasie[2], Dionna M. Fry[1], Meslew Chanyalew[3], Zerihun Tadesse[2], Aisha Stewart[4], Kelly Callahan[4], Elizabeth Rose Mayeda[5], Jeremy Keenan[1]

[1]University of California San Francisco, San Francisco, CA, United States, [2]The Carter Center, Addis Ababa, Ethiopia, [3]Amhara Regional Health Bureau, Bahir Dar, Ethiopia, [4]The Carter Center, Atlanta, GA, United States, [5]University of California Los Angeles, Los Angeles, CA, United States

Diarrhea is a major contributor to global child morbidity and mortality. Most trials measure diarrhea using caregiver-reported symptoms, which are prone to substantial measurement error. Quantitative bias analysis can be used to estimate the direction, magnitude and uncertainty arising from misclassified outcomes. We conducted a cluster-randomized trial of a water improvement intervention in the Amhara region of Ethiopia. Fourteen communities were selected for the trial, with half randomized to a water point intervention and the other half to control. Caregivers were asked to report if children had three or more loose or watery stools in a 24-hour period anytime in the past seven days. We used logit-binomial mixed-effects models with a random effect for community to estimate the effect of the intervention on caregiver-reported diarrhea. We then used probabilistic bias analysis to calculate bias-corrected prevalence ratio (PR) with a specified uniform distribution. 28.6% (42/155) children in the water intervention arm and 24.8% (38/160) of children in the control arm had a reported event of diarrhea [PR = 1.15 (0.69, 1.7), p = 0.571]. The bias-corrected PR was 1.36 (95% CI: 0.87, 4.88) for non-differential misclassification and 1.19 (95% CI: 0.16, 9.98) for differential misclassification. In conclusion, we found no effect of a clean-water intervention on pediatric diarrhea using caregiver-reported symptoms. Probabilistic bias analysis revealed that corrected effect estimates are highly dependent on the specificity of reported diarrhea and are father from the null under differential assumptions compared to non-differential assumptions. Due to the small effect size and wide confidence intervals, probabilistic bias analysis did not reveal a corrected true effect of the water-improvement intervention. Larger trials with more precise effect estimates may be more informative targets form probabilistic misclassification bias analysis.

2028

E. COLI DETECTION, GROWTH, AND DIVERSITY IN HOUSEHOLD SOILS FROM HARARE, ZIMBABWE AND MIRZAPUR, BANGLADESH

Timothy R. Julian[1], Maria Camila Montealegre[1], Tala Navab Daneshmand[2], Subarna Roy[3], Muhammad Iqbal Hossain[3], Franziska Böni[1], Max N. Friedrich[1], Marja Gächter[1], Linn Mlambo[4], Lea Caduff[1], Val F. Lanza[5], Tamuka Nhiwatiwa[4], Hans Joachim Mosler[1], Mohammad Aminul Islam[3]

[1]Eawag, Swiss Federal Institute of Aquatic Science and Technology, Dübendorf, Switzerland, [2]Oregon State University, Corvallis, OR, United States, [3]International Centre for Diarrhoeal Disease Research, Bangladesh, Dhaka, Bangladesh, [4]University of Zimbabwe, Harare, Zimbabwe, [5]Hospital Universitario Ramón y Cajal, Madrid, Spain

Food and environmental compartments (i.e., water, hands, soils) act as intermediates in the spread of *E. coli* pathotypes from infected to susceptible people and animals. Increasingly, *E. coli* - including pathotypes - are detected in soils within or near households. The source of *E. coli* is unclear, with evidence of contributions from both people and animal. However, an overlooked factor may be *E. coli* growth in the external environment. In two studies in Harare, Zimbabwe and Mirzapur, Bangladesh, we investigate *E. coli* in soil collected from household plots. We evaluated isolates from soil and feces (human, chicken, cattle) for growth using soil microcosms and explored phylogenetic relationships based on whole genome sequencing. We found *E. coli* in 63% (n = 142) of soil samples in Harare, significantly higher than the 44% (n = 52) in Mirzapur (p = 0.02). Pathogenic *E. coli* were detected at both sites, with enteroaggregative *E. coli* (2/45 isolates screened) in Harare and shigatoxigenic, enteropathogenic, enteraggregative, and enterotoxigenic *E. coli* (18/175 isolates screened) in Mirzapur. At both sites, there were no or weak associations between *E. coli* in soils and household factors (agricultural/ practices; infrastructure; water, sanitation, and hygiene). In contrast, we found moderate correlations between *E. coli* and soil characteristics (i.e., moisture (Spearman's rho = 0.48, $p < 0.01$ in Mirzapur and rho = 0.36, $p< 0.01$ in Harare) and clay (Spearman's rho = 0.47, p = 0.01 in Mirzapur, not tested in Harare). Soil microcosms showed *E. coli* growth for isolates from both sites, dependent on soil (10 soils tested) but not isolate (4 from Harare, 10 from Mirzapur). Finally, phylogenetic reconstruction revealed high diversity amongst *E. coli* isolates from soil, chicken, human, and cattle in Mirzapur. Specifically, of 60 *E. coli* sequenced, there were 36 sequence types, with no type significantly more prevalent in a particular reservoir. Overall these findings indicate that *E. coli* circulating in domestic settings from different reservoirs are remarkably diverse, capable of growth in soil, and not meaningfully associated with household-level factors.

EFFECT OF A BEHAVIOR CHANGE INTERVENTION TO IMPROVE PERI-URBAN SANITATION QUALITY IN LUSAKA, ZAMBIA: A RANDOMIZED CONTROLLED TRIAL

James B. Tidwell[1], Robert Aunger[1], Roma Chilengi[2], Jenala Chipungu[2]

[1]London School of Hygiene & Tropical Medicine, London, United Kingdom, [2]Center for Infectious Disease Research in Zambia, Lusaka, Zambia

Despite gains in sanitation coverage globally, the prevalence of peri-urban shared sanitation is on the rise in sub-Saharan Africa, and the growth rate of such peri-urban areas is increasing. Only a few studies have rigorously evaluated how to improve sanitation quality, and none have examined improving structural quality in addition to cleaning practices. We did an individually randomized controlled trial in a peri-urban area in Lusaka, Zambia between August 8, 2017 and March 1, 2018. We enrolled 1085 adult landlords on plots where the landlord and at least one tenant household lived. The intervention consisted of a series of group meetings of landlords discussing motivating sanitation quality improvement as a way to build wealth and reduce conflict and the control received no intervention. We measured outcomes one month before the start of the intervention and four months post-intervention through repeated surveys of landlords and tenants. We compared intervention and control groups on an intention-to-treat basis using difference in differences. We found significant impacts on several of our primary outcomes measuring individual sanitation components as well as on a composite measure of overall sanitation quality. Ensuring that intervention landlords attended all meetings and low response rates were major challenges, though these difficulties of working in a peri-urban setting were anticipated, and several different imputation assumptions and exposure adjustments are tested to determine the robustness of the findings. Behavior-change messaging to create demand for improving peri-urban sanitation quality may be a cost-effective tool and should be evaluated in other contexts as a supplement to current widespread infrastructure improvement projects.

2030

DEVELOPMENT OF RECOMMENDATIONS FOR FOMITE DISINFECTION IN CHOLERA OUTBREAKS

Karin Gallandat, Daniele Lantagne

Tufts University, Medford, MA, United States

Fomites are inanimate objects that can become contaminated and transmit infectious agents. Guidelines on how to disinfect fomites in cholera outbreaks, while mostly chlorine-based, are inconsistent in terms of concentration, contact times and recommended practices. We are investigating fomite disinfection in three studies: 1) a systematic review; 2) laboratory experiments; 3) field-based evaluations. The initial database search for the systematic review yielded 9,484 references and data was extracted from 89 studies that met inclusion criteria. Only one study using the cholera agent Vibrio cholerae was identified. Analysis is in process and data relevance to low-resource outbreak settings will be discussed. In the laboratory, we are assessing the efficacy of chlorine against Vibrio cholerae and the indicator Escherichia coli on hard and porous surfaces. Expected results by fall include: 1) whether Escherichia coli is an appropriate surrogate for Vibrio cholerae; 2) whether spraying or pouring a 0.2% chlorine solution can inactivate Vibrio cholerae on surfaces within a given contact time (or what chlorine concentration and contact time should be recommended). Lastly, we have developed a protocol in partnership with Action Against Hunger, Médecins Sans Frontières (Operational Center Amsterdam), and the International Federation of the Red Cross and Red Crescent Societies to evaluate household spraying and household disinfection kits in cholera outbreaks in terms of effectiveness, as measured by surface sampling in situ, and appropriateness. The first evaluation will take place in the Democratic Republic of the Congo in May 2018 and we expect to have preliminary results from at least two evaluations by the time of the conference. In summary, the presentation would provide an overview of currently available data on fomite disinfection efficacy, laboratory data on chlorine efficacy against cholera bacteria, and preliminary results from field evaluations of household disinfection interventions, thus providing an example of a comprehensive strategy to develop evidence-based recommendations for low-resource outbreak settings.

2031

HUMAN WASTES MANAGEMENT IN THE MANGROVE AREAS OF EASTERN OBOLO LGA, NIGER-DELTA, NIGERIA

Inyang A. Atting, Idorenyin D. Usip, Gabriel Umoh

University of Uyo, Uyo - Nigeria, Uyo, Nigeria

A study was carried out on human wastes management in the mangrove areas of Okorombokho, Eastern Obolo LGA, Niger-Delta, Nigeria between the month of March and December, 2017. A total of 340 questionnaires were administered by systematic random sampling technique and all were retrieved. Water samples were also collected from rivers and a stream located in the area and were analyzed using standard laboratory methods, including microbiological analysis. Results show high total heterotrophic bacteria (THB) counts in all the five Stations where water samples were collected, with the lowest count (1×10^2) recorded in Station 1 during dry season and the highest count (103×10^1) observed in Station 5 during wet season. Enumeration of coliform counts revealed that water samples from Stations 1, 2, 3, 4 and 5 had 90MPN/100ml, 90MPN/100ml, 160MPN/100ml, 90MPN/100ml and 160MPN/100ml, respectively for total coliform count during the dry season and 180MPN/100ml for all the five Stations during the wet season. Statistical analysis show that there is significant difference ($P<0.05$) in bacteria count in the values obtained for THB, total coliform and faecal coliform in all the Stations during the study while there is no significant difference for the fungal isolate ($P>0.05$). Values obtained for THB and total coliform counts were above WHO permissible limits for drinking water. Bacteriological identification of 514 isolates obtained from the samples revealed the presence of these genera: *Pseudomonas auruginosa,* 47 (9.14%); *Escherichia coli,* 84(16.34%); *Streptococcus aureus,* 202 (39.30%); *Streptococcus pneumonia,* 165 (32.10%) and *Geotrichum spp, 1*6 (3.11%). This study indicates that this water source is highly polluted due to high presence of faecal coliform and is above WHO standard for drinking water and thus not safe for drinking or domestic use. It is therefore recommended that government should build Central Toilet Systems in this mangrove area and also formulate an effective waste segregation/management policy that will properly curb the unhygienic waste disposal practices in this fast environmentally challenged ecosystem.

2032

SANIPATH-TYPHOID AND ENVIRONMENTAL SURVEILLANCE FOR TYPHOID: A PROTOTYPE FOR LARGE SCALE DEPLOYMENT IN CITIES IN LOW- AND MIDDLE-INCOME COUNTRIES

Suman Kanungo[1], Shanta Dutta[1], Jamie Green[2], Yuke Wang[2], Ashutosh Wadhwa[2], Pranab Chatterjee[1], Suraja Raj[2], Renuka Kapoor[2], James Ebdon[3], Asish Mukhopadhyay[1], Jayanto Saha[1], Christine Moe[2]

[1]ICMR National Institute of Cholera and Enteric Diseases, Kolkata, India, [2]Emory University, Atlanta, GA, United States, [3]University of Brighton, Brighton, United Kingdom

Enteric fever affects millions of people throughout Low- and Middle-Income Countries (LMIC). According to the most recent WHO estimates published in 2014, approximately 21 million typhoid cases and 222,000 typhoid-related deaths occur annually worldwide. The Indian subcontinent has the highest reported incidence of typhoid fever globally. It is vital to develop sensitive lab methods for detection of those pathogens in various environmental samples, build an in-depth understanding of typhoid transmission, and monitor the circulation of *S.* Typhi and *S.* Paratyphi A

in the environment. The SaniPath-Typhoid study (SPT) was conducted in five areas with demographic and geographic variability. Environmental samples from up to 10 sample types were analyzed for *E. coli*, human-specific phage, *S.* Typhi, and *S.* Paratyphi A. Positive samples for *S.* Typhi or *S.* Paratyphi A were archived for genomic characterization and future diversity analysis. A typhoid environmental surveillance (ES) strategy was designed based on results from pilot environmental sample testing and mathematical models. The models incorporated data collected from typhoid ES, data from the city's clinical surveillance, results from the study of *S.* Typhi and *S.* Paratyphi A persistence in different environments, information on population density and sewage system, recovery efficiency during sample processing, and detection sensitivity. The models provide guidance on the selection of ES sampling sites. The ES will be conducted in the same areas covered by active typhoid clinical surveillance (Ward 58 and Ward 59) as well as throughout the entire city of Kolkata. A total of 1250 and 6500 samples will be analyzed over a 2-year period during SPT and ES, respectively. The results of the SPT and ES will provide critical information about the risk of typhoid transmission through different environmental pathways and about *S.* Typhi and *S.* Paratyphi A circulation in the environment in endemic settings with vulnerable resident populations. This study will enable evidence-based decisions about vaccine and water, sanitation, and hygiene interventions.

2033

SUCCESSFUL APPLICATION OF MICROBIAL SOURCE TRACKING USING GB-124 BACTERIOPHAGE AS AN INDICATOR OF HUMAN FECAL CONTAMINATION IN ENVIRONMENTAL SAMPLES IN KOLKATA, INDIA

Ashutosh Wadhwa[1], Shanta Dutta[2], James Ebdon[3], Goutam Chowdhary[2], Renuka kapoor[1], Yuke Wang[1], Asish Mukhopadhyay[2], Suman Kanungo[2], Pranab Chatterjee[2], Christine L. Moe[1]

[1]Emory University, Atlanta, GA, United States, [2]National Institute of Cholera and Enteric Diseases, Kolkata, India, [3]University of Brighton, Brighton, United Kingdom

Fecal indicator bacteria (FIB) have been used for over a century to connote potential fecal contamination. However, FIB may not correlate well with the presence of human enteric pathogens when nonhuman fecal sources are present. To address this need, microbial source tracking (MST) using bacteriophage of the *Bacteroides* spp. can serve as a reliable method to indicate human fecal contamination and be used to examine the risk of exposure to pathogens of human origin. The objective of this study was to investigate the presence and abundance of bacteriophage against a strain of *Bacteroides fragilis* (GB-124) in different environmental samples as well as in animal fecal samples in Kolkata, India. During the preliminary phase, we tested 28 sewage samples collected from different parts of Kolkata and evaluated them in 4 serial dilutions for the presence of phage against the GB-124 *Bacteroides* host. These samples ranged from very concentrated sewage collected from the manholes to drain water collected after heavy rain. Phage against the GB-124 *Bacteroides* host species were detected in 26 of the 28 samples. The phage concentration ranged from 200 to 50,000 plaques per mL (PFU/mL). The 2 samples that had no detectable phage against the GB-124 host were collected from an urban pig farm. This is the first report of a phage-based MST technique used successfully in India. Our results suggest that, although the host strain GB-124 is geographically constrained, it is present in high concentrations (up to 50,000 PFU/mL) in Kolkata and thus can be used as an effective technique to differentiate origin of fecal contamination. GB-124 phage can provide a sensitive, specific, quantitative, low-cost and rapid culture-based MST method to identify human fecal contamination in an urban setting with dense human and animal populations. Next steps include: 1), testing additional samples from a range of animal species commonly found in Kolkata to further confirm that GB-124 is human specific in this setting, and 2) examining 12 different types of environmental samples to detect the presence of human fecal contamination.

IMPACT OF A LARGE HEALTH SYSTEMS STRENGTHENING PROJECT ON THE PREVALENCE OF DIARRHEAL DISEASE IN UNDER-FIVE CHILDREN IN THE DEMOCRATIC REPUBLIC OF THE CONGO

Andrea L. Smith[1], Janna Wisniewski[1], Leslie Craig[1], Sara Iguodala[1], David Hotchkiss[1], Paul Lusamba[2], Joshua Yukick[1]

[1]Tulane University, New Orleans, LA, United States, [2]Tulane International L.L.C, Kinshasa, Democratic Republic of the Congo

The Access to Primary Health Care (ASSP) project was implemented between 2014 and 2017 in order to improve reproductive, maternal, neonatal and child health, while strengthening the overall delivery and quality of health services in the Democratic Republic of the Congo. ASSP worked across five provinces in 52 health zones, targeting those where ASSP's predecessor project had been implemented and those with relatively weak health systems. ASSP strategies included enhancing health facility infrastructure and availability of services, providing community-based health interventions, revitalizing community health committees, improving health education, and increasing sustainable access to safe drinking water and improved sanitation. A quasi-experimental community level panel design with intervention and matched comparison health areas, utilizing population-based surveys conducted in 2014 and 2017, was used to evaluate the effects of the program on WASH related outcomes. The impact of exposure to ASSP on period prevalence of diarrheal disease among under-five children was tested using a difference-in-differences approach in a logistic regression model. Although, only 13.2% of intervention villages received a water, sanitation and hygiene (WASH) intervention, the period prevalence of diarrheal disease fell by 8.6 percentage points among under-five children in ASSP areas when compared to matched comparison areas (p=0.006). Project mechanisms that likely attributed to the decreased prevalence of diarrhea include increased use of safe drinking water sources and improved sanitation at the household level, enhancement of water and sanitation facilities at health centers and increased community participation in health services. Future work will include a sub-analysis of villages that received WASH specific interventions to measure any additional impact of the community-led total sanitation intervention.

2035

THE OROMIA TRACHOMA F AND E STRATEGY: A CASE EXAMPLE OF EMERGING PREFERRED PRACTICE

Sarity Dodson[1], Anne Heggen[2], Amanuel Atomsa[2], Cindiya Sivasubramaniam[3], Zelalem Jemel[2], Virginia Sarah[4], Hirpa Miecha[5]

[1]The Fred Hollows Foundation, Melbourne, Australia, [2]The Fred Hollows Foundation, Addis Ababa, Ethiopia, [3]The Fred Hollows Foundation, Sydney, Australia, [4]The Fred Hollows Foundation, London, United Kingdom, [5]Oromia Regional Health Bureau, Addis Ababa, Ethiopia

Trachoma is a neglected tropical disease (NTD) and the leading infectious cause of blindness globally. The WHO-endorsed SAFE strategy (Surgery, Antibiotics, Facial Cleanliness and Environmental Improvement) provides a framework to guide trachoma elimination efforts with all four components necessary for effective disease control. Oromia in Ethiopia is the most trachoma-endemic region, in the most trachoma-endemic country in the world. In 2017, the need for a new F and E strategy for Oromia was recognised. Building upon the International Coalition for Trachoma Control's (ICTC) guiding principles for F and E and lessons learned from previous programming, and drawing upon theory and process frameworks common practice in health promotion and behavioural science, a new region wide approach to F and E programming was proposed. The approach seeks to find a balance between the importance of contextualised, locally relevant solutions and the need to deliver to scale an effective region wide F and E program. The Oromia trachoma F and E strategy comprises several components: 1) guiding principles; 2)

program elements; 3) outcome statements and associated indicators; and 4) a program planning approach. This paper provides an overview of the F and E strategy and its development, discusses its implications for other trachoma programs, and identifies next steps towards preferred practice in trachoma F and E programming.

THE ASSOCIATION BETWEEN COMMUNITY-LEVEL SANITATION ACCESS AND ANEMIA IN WOMEN AGE 15-49 YEARS

Brittany L. Kmush[1], Anushruta Neupane[1], Carolina F. Mendez-Rodriguez[1], Catherine Dobens[1], Mahwish Iqbal[2], David A. Larsen[1]

[1]Syracuse University, Syracuse, NY, United States, [2]SUNY Upstate Medical University, Syracuse, NY, United States

Lack of sanitation facilities enables fecal-oral transmission of pathogens that can lead to poor health outcomes, including anemia. Sanitation access is typically monitored at the household level, however recent evidence suggests that community level sanitation access (CSA) may be an important driver of health, even for those with household sanitation. In order to assess how community-level and household-level sanitation access affect women's anemia status, we conducted an individual-level meta-analysis of cross-sectional surveys. We retrieved information from all publically available demographic health surveys as of July of 2017 that measured anemia in women 15-49 years old (smoking and altitude adjusted hemoglobin <12g/dl in non-pregnant women, <11g/dl in pregnant women). We matched women within datasets on several individual and community covariates to account for selection bias. We estimated the association between anemia and household and CSA utilizing a generalized linear model with the matched group as a random intercept (adjusting for dataset). 619,016 women from 93 surveys from 42 countries from 1997-2016 had recorded anemia status. After matching, there were 578,995 women in 1,356 matched groups. The prevalence of anemia was lower among women in communities with higher access to sanitation, whether or not the woman had access to household sanitation (χ^2 p-value <0.001). For women without household sanitation, the odds of anemia were decreased in communities with higher CSA, OR: 1.09 (0% CSA), Ref. (1-30% CSA), 0.92 (31-60% CSA), 0.94 (61-99% CSA) (p-value <0.001 for all). The same pattern was seen in women with household sanitation although not statistically significant except for those living in communities with complete CSA, OR: Ref (1-30% CSA), 0.97 (31-60% CSA, p-value: 0.275), 0.98 (61-99% CSA, p-value: 0.296), 0.95 (100% CSA, p-value: 0.03). Women are more likely to be affected by anemia in communities with lower CSA, especially among women without household sanitation. When estimating the benefits of eliminating open defecation, it is important to consider both the community and household level impacts.

2037

WATER, SANITATION, AND HYGIENE ACCESS IN SOUTHERN SYRIA: ANALYSIS OF SURVEY DATA AND RECOMMENDATIONS FOR RESPONSE

Mustafa Sikder[1], Umar Daraz[2], Daniele Lantagne[1], Roberto Saltori[3]

[1]Tufts University, Medford, MA, United States, [2]UNICEF, Amman, Jordan, [3]Independent consultant, Amman, Jordan

Water, sanitation, and hygiene (WASH) are immediate priorities for human survival and dignity in emergencies. In 2010, before the ongoing conflict, Syria had >90% access to safe drinking water. The WASH response in Syria aims to reduce disease transmission risk in this middle-income context by maintaining: 1) the functionality of preexisting WASH infrastructure and, 2) safety of alternative trucked water. The objective of this study was to assess the impact of these risk reduction programs. In 2016 and 2017, respectively, 1,281 and 1,360 household surveys were conducted in Southern Syria to collect information on demographics, WASH access, drinking water free chlorine residual (FCR), and reported <5 years old children diarrhea. We built regression models to study associations between demographic and WASH variables with FCR presence and diarrheal incidence. Piped water as the main source declined from >90% in 2010 to 22% in 2016 and 15% in 2017; private sector trucked water filled this supply gap. Households accessed 50-60 liters of water/ person daily and spent ~20% of income on water. FCR presence in stored water increased from 4% in 2016 to 28% in 2017, with receiving risk reduction programming strongly associated with FCR presence (OR 24, 95% CI 6-99). Access to sanitation and hygiene were also protective against childhood diarrhea. Based on these correlations between risk reduction programs and outcomes, we are conducting a follow-up study to understand the relative impact of risk reduction interventions i.e. chlorine distribution and training, awareness campaigns, chlorinators at wells, and trucker incentive. The data were collected from four intervention groups implementing different combinations of these activities and a control group. Analysis to compare relative impacts of these strategies is ongoing; both studies would be presented at the meeting. In summary, appropriate WASH intervention can improve water quality and reduce disease in emergencies. Lessons from this protracted emergency response in a middle-income context with preexisting WASH services will provide insights for future WASH response design in similar context.

2038

A SPATIALLY EXPLICIT RISK ASSESSMENT OF FACTORS IMPACTING DRINKING WATER QUALITY IN RURAL BANGLADESH

Varun Goel[1], Md. Sirajul Islam[2], Md. Yunus[2], Griffin Bell[1], Sumati Sridhar[1], Michael E. Emch[1], Mark D. Sobsey[1]

[1]University of North Carolina Chapel Hill, Chapel Hill, NC, United States, [2]International Centre for Diarrhoeal Disease Research, Bangladesh, Dhaka, Bangladesh

Most rural Bangladeshis source their drinking water from shallow tubewells as an arsenic mitigation approach. However, these wells are found to have poorer water quality and are associated with higher incidence of diarrheal diseases. The alternative mitigation approach—sourcing from deep tubewells—has demonstrated protection against arsenic exposure and offers improved water quality. However, the health effects of transitioning to these sometimes more distant and less accessible wells have not been adequately investigated. Using a combination of household surveys, geospatial data, and environmental microbiological data, we follow a prospective cohort of 500 households (250 shallow and 250 deep tubewell users) over two years to examine under what conditions deep tubewells are most protective against microbial contamination and diarrheal disease. Preliminary baseline results suggest that despite procuring water from sources with very low contamination at source, 50% households drank contaminated water. We ran Mann-Whitney tests to confirm that deep tubewell users were at lower risk of water storage contamination compared to shallow tubewell users. However, among the 40% deep tubewell households drinking contaminated water, we found that on average, they stored water longer, and had significantly higher travel time and distances to their drinking water source, compared to other households. These results suggest that although deep tubewells may protect against poor household drinking water quality, impediments to access such as longer distance and lack of ownership modify handling and storage, subsequently increasing the possibility of microbial contamination. Next, we will incorporate other contextual factors such as perceived barriers to access, seasonality, household wealth, and the sanitation environment from baseline and follow-ups to examine the ecological context under which deep tubewells modify microbial contamination risk. With increasing interest in installing more deep tubewells as an arsenic mitigation intervention, our results offer considerations for policymakers in rural Bangladesh and beyond.

QUALITATIVELY DIFFERENT ENTERIC PATHOGEN RESERVOIRS AND TRANSMISSION PATHWAYS ARE ASSOCIATED WITH CHILDHOOD GROWTH IN THE KENYAN AND GAMBIAN SITES; AN ANALYSES OF THE GLOBAL ENTERIC MULTICENTER STUDY

Kurt Z. Long[1], Abu S. Faruque[2], Chris Stride[3], Inong R. Gunanti[1], J. Johanna Sanchez[4], Salvador Zamora[5], Georgina Mora[6], James P. Nataro[7], Dilruba Nasrin[8], Myron Levine[8], Karen Kotloff[9]

[1]Swiss Tropical and Public Health Institute, Basel, Switzerland, [2]International Centre for Diarrhoeal Disease Research, Bangladesh, Dhaka, Bangladesh, [3]The Institute of Work Psychology, University of Sheffield, Sheffield, United Kingdom, [4]Child Health Research Centre, Faculty of Medicine and Biomedical Sciences, University of Queensland, Brisbane, Australia, [5]Mathematics Department, UNAM, Mexico City, Mexico, [6]Secretariat of Health, Xalapa, Mexico, [7]Department of Pediatrics, University of Virginia School of Medicine, Charlottesville, VA, United States, [8]Department of Medicine, University of Maryland School of Medicine, Baltimore, MD, United States, [9]Development and Department of Pediatrics, University of Maryland School of Medicine, Baltimore, MD, United States

Important reductions have occurred in childhood growth impairment in many Sub-Saharan countries but reductions are not uniform across the region. Further reductions may be possible through the development of targeted precision health interventions based on an understanding off causal relationships between household risk factors, enteric pathogen transmission and childhood growth. Associations of potential household pathogen transmission pathways with HAZ were tested using structural equation models (SEM) in the rural communities of Nyanza Province, Kenya and Basse, the Gambia that were part of Global Enteric Multicenter Study (GEMS). Models first tested whether household pathogen reservoirs had direct effect on height-for-age z-scores (HAZ) or were mediated by enteric infections. Models then tested whether hygiene behaviors and improved water sources reduced pathogen transmission and children's exposure and so moderated these indirect associations. A total of 3,359 children were enrolled in Kenya and 2,598 enrolled in the Gambia. In Kenya, unimproved toilet facilities was negatively associated with HAZ while water storage had a direct negative association and an indirect association mediated by *Giardia* infection. Sheep, goats and rodents in the compound had indirect negative associations with HAZ mediated by *Giardia* and Enteropathogenic *E. coil* (EPEC) infections. Associations were reduced through elimination of infections by specific handwashing behaviors and household improved water sources. In Gambia, unimproved toilet facilities had an indirect negative association with HAZ via ETEC, *Cryptosporidium* and *S. flexneri* infections but handwashing after handling animal reduced this effect through elimination of infections. These differences in household pathogen reservoirs and corresponding pathways between the sites may result from differences in community infrastructure and economies. Targeted health interventions may more effectively reduce childhood growth impairment in these two countries using household level estimates of pathogen transmission and exposure risk derived from these models.

FINE-SCALE SPATIO-TEMPORAL VARIATION IN PNEUMOCOCCAL PNEUMONIA BURDEN IN CHILDREN IN AFRICA IN THE ERA OF THE PNEUMOCOCCAL CONJUGATE VACCINE

Robert C. Reiner, Daniel Casey, Christopher Troeger, Mat Baumann, Brigette Blacker, Jon Mosser, Steven Lim, Simon Hay

University of Washington, Seattle, WA, United States

In 2000, pneumococcal pneumonia was responsible for 281,200 deaths in children under the age of five in Africa. By 2016, this decreased to 177,700. This is even more impressive when considering population growth across the continent - the mortality rate decreased from 25 per 10,000 to 11 per 10,000. In spite of this gain, pneumococcal pneumonia remains the most common etiology of lower respiratory infections across Africa (and globally). There are numerous reasons pneumococcal pneumonia burden has declined in Africa. Along with improved nutritional indicators and lower exposure to indoor air pollution, the introduction of the pneumococcal conjugate vaccine (PCV) has had a substantial impact in reducing risk in multiple countries. Zambia, for example, saw their under-5 mortality rate associated with pneumococcal pneumonia drop from 64 per 10,000 to 22 per 10,000 (their 2016 PCV coverage was estimated to be 87%). Conversely, several countries in the central Sahel have not yet introduced PCV, and while they have experienced some decline in the past 16 years, it is considerably slower than their neighbors. Here, leveraging house-hold surveys on both lower respiratory infection prevalence and vaccine coverage, applying Beysian geostatistical techniques and integrating the Global Burden of Disease project, we produce continent-wide estimates of fine-scale variation in pneumococcal pneumonia burden from 2000 to 2016. In addition to identifying substantial sub-national variation in burden across numerous African countries, we identify risk factors associated with these variations. In general, areas with high indoor air pollution and poor nutritional indicators are more likely to have high pneumococcal pneumonia burden, but there are regions were these risk factors are mitigated with PCV. As with our work on overall lower respiratory infection burden in Africa, we identify a concentration of risk to a few countries in the Sahel. Fine-scale estimates of burden are a necessary tool for public health interventions. These results should be used to identify optimal targeting strategies to reduce the burden of this vaccine-preventable infection.

2041

A GENE EXPRESSION SIGNATURE ACCURATELY IDENTIFIES VIRAL ACUTE RESPIRATORY INFECTIONS IN A SRI LANKAN POPULATION

L. Gayani Tillekeratne[1], Sunil Suchindran[1], Emily R. Ko[1], Elizabeth A. Petzold[1], Champica K. Bodinayake[2], Ajith Nagahawatte[2], Vasantha Devasiri[2], Ruvini Kurukulasooriya[2], Megan E. Reller[1], Bradly P. Nicholson[1], Micah T. McClain[1], Thomas Burke[1], Ephraim L. Tsalik[1], Ricardo Henao[1], Geoffrey S. Ginsburg[1], Christopher W. Woods[1]

[1]Duke University, Durham, NC, United States, [2]Faculty of Medicine, University of Ruhuna, Galle, Sri Lanka

Viral acute respiratory infections (ARI) are commonly treated with antibiotics due to limitations with pathogen-based diagnostics. A host-based, reverse transcription polymerase chain reaction (RT-PCR) gene expression signature identified viral ARI with 90% accuracy in a US population. We determined signature performance in a Sri Lankan population. We enrolled febrile patients in Sri Lanka from Jul '12-May '13 and collected nasopharygeal samples, serum, and blood in PAXgene RNA tubes. We confirmed influenza using multiplex PCR (Luminex NxTAG). We phenotyped patients with a non-infectious syndrome if testing excluded respiratory viruses, dengue, leptospirosis, and rickettsial illnesses and they had a non-infectious clinical diagnosis. We extracted total RNA and performed host RNA sequencing (Illumina). We aligned reads to hg38 reference genome using Bowtie2, quantified at isoform level using Express version 1.5.1, and normalized using trimmed-mean normalization. We mapped genes from the prior signature to RefSeq transcripts and summed isoforms to obtain gene-level expression estimates. We used the limma-voom framework to assess differential expression. We used the first principal component of all genes to generate a score and assessed difference using a t-test. Among 29 patients with influenza and 3 patients with non-infectious syndromes, median age was 35.2 years (IQR 21.4-55.8) and 50% were male. Median duration of fever was 4 days and 72% patients received antibacterial therapy. Twenty-five genes from the prior signature were identified; 20 were different in patients with viral vs non-infectious syndromes ($p<0.05$). The small sample limited our ability to fit

a model and assess resampling-based performance. The summary score (79% explained variance by first principal component) differed between groups (p<0.001) and high discrimination was observed (AUROC=0.95). A gene expression signature performed well at identifying viral ARI versus non-infectious illness in a Sri Lankan population. Host-based diagnostics may play an important role in identifying viral ARI and reducing inappropriate antibiotic use globally.

2042

MAPPING LOWER RESPIRATORY INFECTIONS IN SPACE AND TIME ACROSS AFRICA, 2000 - 2016

Daniel C. Casey, Scott J. Swartz, Christopher E. Troeger, Brigette F. Blacker, Mat M. Baumann, Nicholas Graetz, Simon I. Hay, Robert C. Reiner

IHME, Seattle, WA, United States

Lower respiratory infections (LRI) are the second largest cause of disease burden for children under five in Africa, responsible for more than 327,000 deaths and 2,850,000 severe infections in 2016. Previous efforts to understand the spatiotemporal burden of LRIs lack either the spatial breadth or fine spatial resolution presented here. Annual estimates of LRI prevalence, incidence, and mortality among children under five years old were produced with high geographic detail (5-km^2) across Africa from 2000 to 2016. Estimates were created using geolocated survey clusters from 201 household surveys, a suite of environmental and socio-demographic covariates, Bayesian geostatistical techniques, and calibrated to the Global Burden of Diseases, Injuries, and Risk Factors Study (GBD) 2016 results. In 2016, estimated deaths due to LRIs in first administrative subdivisions ranged from less than one in Al Kufrah, Libya to 8,070 (95% UI 7930–8230) deaths in Oromia in Ethiopia. The highest mortality rates were estimated to occur in Juba Hoose (11 per 1,000 (95% UI 9 – 12)) and Juba Dhexe (10 per 1000 (95% UI 9 – 12)) in Somalia and Mont de Lam (8 per 1,000 (95% UI 7 – 9)) and Barh Koh (8 per 1,000 (95% UI 7 – 9)) in Chad. These two countries, along with Central African Republic are the current *Foci* of LRI mortality in Africa. Juba Hoose and Juba Dhexe also feature highest estimated rates of severe incidence at 45 per 1,000 (95% UI 40 – 51) and 41 per 1,000 (95% UI 36 – 47) respectively. Our findings identify substantial spatial and temporal variation in the burden of LRI on the African continent. However, we also note the increasing concentration of disproportionate burden due to LRIs in the central part of the continent—just south of the Sahel. These results expose areas of high burden, stagnation, and uncertainty. They should be used to guide targeted interventions within and between countries, assess the effectiveness of current strategies and plan data collection efforts.

2043

CLIMATE VARIABILITY AND CHILDHOOD PNEUMONIA IN RURAL BANGLADESH: A TIME SERIES ANALYSIS

Mohammad Zahid Hossain[1], Al Fazal Khan[2], Wenbiao Hu[1]

[1]Queensland University of Technology, Australia, Brisbane, Australia, [2]International Centre for Diarrhoeal Disease Research, Bangladesh, Dhaka, Bangladesh

Pneumonia is the leading cause of mortality and morbidity for children under the age of 5 years old in developing countries. Very few studies have assessed the association between climate factors and child pneumonia in a climate vulnerable country like Bangladesh. The research aimed to examine the relationship between climate variability and childhood pneumonia in rural Bangladesh and compare the difference of the climate effects on pneumococcal conjugate vaccines (PCV) intervention. Weekly data on pneumonia cases and climate variables (temperature and relative humidity) were collected from the Matlab hospital icddr,b and Bangladesh Meteorological Department, respectively during 1st January 2012 and 31st December 2016. Time series cross-correlation functions were applied to identify the time lags of the effect of each climate factor on pneumonia. Time series generalized linear regression model (GLM) with Poisson link was used to quantify the relationship between climate factors and childhood pneumonia. Moreover, the study was divided into two research periods by the introduction of PCV in national immunization program. A total of 2,655 pneumonia cases were admitted during the study period. Our results showed that before PCV intervention (average 717 cases per year), only temperature (relative risks (RR): 0.966, 95% Confidence Interval (CI): 0.955-0.976) was significantly associated with child pneumonia but after PCV intervention (average 252 cases per year) both temperature (RR: 0948, 95% CI: 0.916-0.980) and relative humidity (RR: 0.972, 95% CI: 0.956-0.990) had the significant association with child pneumonia after adjustment of seasonality in the model. The results of this study suggested that weather variability may have played a significant different role in children pneumonia before and after PCV intervention. This results will help to develop the framework of early warning model based on climate factors for pneumonia infection in under developed country like Bangladesh.

2044

DEVELOPING A NOVEL DEEP LEARNING BASED CAVITY DETECTION ALGORITHM FOR TUBERCULOSIS SCREENING ON CHEST XRAYS

Justy Anthony Chiramal, Preetham Putha, Manoj TLD, Bhargava Reddy T, Prashant Warier

qure.ai, Mumbai, India

Tuberculosis is the number one killer among infections accounting for ~1.6 mn deaths in 2016. Chest Xray is one of the most important screening tools for both Pulmonary and Extrapulmonary TB. With scarcity in X ray reading skills in Resource limited settings, its high time that we had automated reporting aiding in early diagnosis. Deep learning, particularly Convolutional Neural Networks(CNN) have shown promising results in identifying abnormalities on images. Though any CXR abnormality needs to be screened for TB, Cavity being one of the most common finding, we developed a 3 stage pipeline for detecting cavity from CXRs. a) Extract overlapping patches in the lung roughly corresponding to the three zones by using a thorax segmentation model. b) Classification of extracted patches as normal/containing cavity. c) Combining patch level predictions with a random forest classifier to reach a scan level prediction. For a, 750 CXRs were manually annotated and a segmentation model(UNET) was trained to emit masks for left and right thoraces separately. These masks were used to extract 3 overlapping patches from either side generating six patches that cover the entire lung area in a CXR. For b, 884 images containing cavities were annotated on a pixel level to create a cavity mask. The patches generated in a were assigned 'cavity yes/no' ground truths based on these annotations. Similarly, patches were extracted from images that do not have cavity and assigned a 'cavity no' ground truth. The dataset thus created was used to train a CNN to detect the presence/absence of cavity in a particular lung patch. These patch level predictions are used as features to train a final random forest classifier to obtain scan level predictions for cavity detection in c. On a testset, the Area under the ROC curve is 0.90 for the detection of cavity whereas the sensitivity at a specificity of 90 was 81. This novel approach of segmenting thorax into overlapping patches improves upon the current black box classification approaches. This algorithm alongside automated detection for other abnormalities on CXR, could be a significant milestone in the early diagnosis strategy towards ending TB.

2045

INFLUENZA INCIDENCE, PREVALENCE, AND MORTALITY ONE HUNDRED YEARS AFTER THE 1918 GLOBAL PANDEMIC: RESULTS FROM THE GLOBAL BURDEN OF DISEASE 2017

Christopher Troeger, Ibrahim Khalil, Brigette Blacker, Stephanie R. Zimsen, Jonathan Brown, Nicholas Kassebaum, Simon I. Hay, Robert C. Reiner

Institute for Health Metrics and Evaluation, Seattle, WA, United States

On the 100th anniversary of the 1918 global influenza pandemic, the virus still represents a significant burden of disease and a looming threat for another global epidemic. The Global Burden of Diseases, Injuries, and Risk Factors Study 2017 (GBD 2017) is a systematic, scientific effort to measure the burden of lower respiratory infections (LRIs) and their etiologies, including influenza. Influenza was attributed to episodes, hospitalizations, and deaths due to lower respiratory infections using a counterfactual approach wherein the modeled frequency of influenza in LRIs and the association between influenza and LRI were assessed to create a population attributable fraction. We estimated separate PAFs for episodes, hospitalizations, and deaths due to LRI attributable to influenza. The GBD study enforces internal consistency between incidence and mortality to create directly comparable estimates for cases, hospitalizations, and deaths due to influenza LRI. In 2017, influenza was responsible for 121,000 deaths (95% UI 96,000-142,000) and 39,547,000 episodes of LRI (95% UI 30,787,000-49,691,000). Over half of influenza LRI deaths occurred among adults over 70 years old (63,000 deaths, 95% UI 51,000-74,000) including nearly 3000 deaths among this age group in the United States (2,800, 95% UI 2,400-3,200). Influenza was less frequently associated with hospitalized episodes of LRI than non-hospitalized episodes and was responsible for 2,843,000 LRI hospitalizations (95% UI 1,569,000-4,908,000), a rate of 0.38 per 1,000 (95% UI 0.21-0.66) and for 24,506,000 hospital-days (95% UI 10,295,000-55,606,000). Influenza was responsible for about 12% of all LRI episodes and represented a greater share of episodes across all ages including nearly 15% in adults 15 to 49 years and 10% among adults over 65 years. Our results suggest that influenza is an important cause of lower respiratory infections globally and particularly among adults over 70. Expanded access to the seasonal influenza vaccine and the development of a universal influenza vaccine may help alleviate some of the significant burden of disease due to influenza LRI.

2046

HARNESSING MOBILE PHONES TO DEVELOP A RESPIRATORY DISEASES EVENT-BASED SURVEILLANCE SYSTEM IN RURAL BANGLADESH: A PILOT STUDY

Md. Golam Dostogir Harun[1], Syeda Mah-E- Muneer[1], Kamal Hossain[1], Md. Habibullah Fahad[1], Md. Habibur Rahman[1], Md. Hafizur Rahman[1], Dr. Sharifa Nasreen[2], Nadia Ali Rimi[1]

[1]Programme for Emerging Infections, Infectious Diseases Division, International Centre for Diarrhoeal Disease Research, Bangladesh (icddr,b), Dhaka, Bangladesh, [2]Department of Epidemiology and Biostatistics, Schulich School of Medicine & Dentistry, Western University, Canada, Dhaka, Bangladesh

Community event-based surveillance (CEBS) is the organized and rapid capture of information from communities about events that pose potential public health risks. We piloted a CEBS to collect information on respiratory symptoms via mobile phone Short Message Service (SMS) to explore the functionality and feasibility of the system. Between March 2014 and October 2015, we recruited and trained 104 community members from 5 villages from 5 districts in Bangladesh, including drug sellers, religious leaders, school teachers, backyard and commercial poultry raisers and veterinarians to send information on respiratory symptoms and disease outcome in humans, as well as in birds with potential exposure risks to human. Each group had a target to send an SMS to icddrb server ranging from daily to weekly irrespective of occurrence of an event. SMS costs were reimbursed. We conducted a formative study and an end-line survey to identify key motivators and barriers for participation in the study. Of the 104 study participants, 99 (95%) sent a total of 2820 (65% of target) SMS about respiratory symptoms. No major technical difficulties were reported. Religious leaders were the most consistent, sending 78% (121/156) of all SMS, but required frequent reminders and/or extensive training, followed by drug sellers, who were the most enthusiastic participants, with 69% (1328/1936). Backyard poultry raisers were the lowest reporting group with 57% (810/1415). Participants with higher educational status were more likely to send SMS regularly (p=0.001). The study participants' motivation factors associated with sending SMS were positive encouragement from community (89%, 95% CI: 87-95%), well-being of the country (84%, 95% CI: 76-91%) and quick response during an outbreak (67%, 95% CI: 57-76%). Forgetfulness (76%) and difficulty in using SMS system (19%) and were found to be the most reported barrier, and interestingly, the SMS reimbursement scheme was not perceived as a barrier. The event-based surveillance system using mobile phone networks through voluntary participation is functional and feasible in Bangladeshi rural communities.

Plasmodium falciparum undergoes asexual reproduction within the human host but reproduces sexually within its vector host, the *Anopheles* mosquito. In regions of moderate to high malaria transmission, infectious mosquito bites occur frequently and human infection typically consists of multiple parasite clones. Under these conditions, cross-fertilization between genetically distinct parasite gametes may occur more frequently than inbreeding within the mosquito midgut, possibly contributing to high genetic diversity of the parasite population. Although generation of genetic diversity arises within mosquitoes, few empirical studies have characterized the proportion of mixed infections in natural mosquito populations and the degree of inbreeding of co-infecting parasite clones within single mosquitoes. Measuring these parameters is critical to understanding how malaria parasite diversity arises within mosquitoes and the ecological mechanisms that drive parasite diversification. This information has profound implications for predicting transmission outcomes and parasite evolution. We used a multiplexed hybrid capture technique to selectively enrich and deep sequence whole *P. falciparum* genomes directly from 28 field-caught *Anopheles funestus* mosquitoes from a high transmission setting in Nchelenge District, northern Zambia. Across the sequenced samples, we obtained a mean of 72% of *P. falciparum* genomes covered at > 5x. A high proportion of *P. falciparum* polygenomic infections was found in mosquitoes based on genome-wide signal. A negative correlation was observed between parasite load and complexity of infection, suggesting interactions between parasite clones. Some of the polyclonal infections were comprised of unrelated parasite genomes. Population genomic studies of mosquito-derived *P. falciparum* samples can greatly aid understanding of transmission dynamics by

clarifying the role of mosquitoes in modulating parasite diversity at the population level and by detecting potential cotransmission of unrelated parasites through a single mosquito blood meal.

HAPLOTYPES OF AUTOPHAGY RELATED-GENE 10 (*ATG10*) PROMOTER POLYMORPHISMS INFLUENCE SUSCEPTIBILITY TO SEVERE MALARIAL ANEMIA IN KENYAN CHILDREN FROM A HOLOENDEMIC TRANSMISSION REGION

Caroline Ndege[1], Qiuying Cheng[2], Karol Dokladny[2], Elly O. Munde[1], Angeal O. Achieng[1], Evans Raballah[3], Collins Ouma[1], Christophe G. Lambert[2], Prakasha Kempaiah[2], Douglas J. Perkins[2]

Severe malarial anemia (SMA, hemoglobin<5.0 g/dL, with any density parasitemia) is a leading cause of global morbidity and mortality among children under 5 years of age residing in *Plasmodium falciparum* holoendemic transmission regions. The molecular pathways that promote SMA are only partially understood. To identify molecular pathways that mediate the development of SMA, we performed GWAS and global transcriptomics in a subset of children with polarized distributions of mild and severe malaria. The global genomic studies revealed Autophagy Related Gene (*ATG)-10* as an important target for validation. Although largely unexplored in human malaria, autophagy is a fundamental cellular process which maintains homeostasis, protein degradation, and production of inflammatory mediators. ATG10, an ubiquitin-conjugating enzyme (E2)-like protein, is crucial for autophagosome elongation. We explored the relationship between *ATG10* promoter polymorphisms [rs2406905 (G-7723T), rs4391141 (T-4322A), and rs1023969 (G-2442C)] and susceptibility to SMA in a pediatric malaria cohort (n=1,313, 2-49 mos.) from western Kenya (holoendemic). Logistic regression analyses (controlling for anemia-promoting cofactors) revealed that carriage of the TAG haplotype was associated with significant protection against SMA, whereas carriage of the GTC, GTG, and TTC haploytpes were associated with significant susceptibility to SMA. Additional experiments in cultured human PBMCs from malaria-naïve donors revealed that phagocytosis of hemozoin (*Pf*Hz) caused a dose- and time-dependent increase in *ATG10* gene expression. Collectively, these findings demonstrate that ATG10 promoter haplotypes influence susceptibility to SMA, and that phagocytosis of hemozoin appears to activate the autophagy pathway.

PLASMODIUM EVOLUTION AND GENETIC DETERMINANTS OF HOST SPECIFICITY IN ESSENTIAL INVASION GENES

Sasha V. Siegel, Francis Galaway, Gavin J. Wright, Julian C. Rayner

Wellcome Trust Sanger Institute, Hinxton, United Kingdom

The genus *Plasmodium* is comprised of highly species-specific protozoan parasites that cause malaria, and affects a wide range of terrestrial vertebrates including humans. The transition and adaptation to new hosts represents a major driving force for parasite evolution, yet little is known about the molecular factors that constrain individual *Plasmodium* species to infecting a single vertebrate host. It was recently shown that the deadliest human-infective *Plasmodium* species, *P. falciparum* evolved from an ape-infective *Plasmodium* ancestor and belongs to the subgenus *Laverania*, whose other members infect African apes. This ape-to-human host transition for the parasite signifies a defining moment in its evolutionary history, and in order to understand the context of this critical host-switching event, we are using both protein binding assays and experimental genetics to explore species-specificity within the PfRH5 complex across the *Laverania* subgenus. In a recent publication from our lab and others on the sequencing of cryptic ape *Plasmodium* species, it was found that horizontal gene transfer between ancestral *Laverania* species likely resulted in the transference of two essential invasion genes - CyRPA (cysteine-rich protective antigen) and RH5 (reticulocyte binding-like homologous protein 5), which could have conferred a fitness advantage that predisposed *P. praefalciparum* to infect humans. In order to evaluate the role of these two essential invasion genes in host specificity, we implemented a strategy that uses inducible diCre recombinase-mediated conditional deletion of *P. falciparum* CyRPA and attempted genetic complementation to rescue parasite lethality with *Laverania* CyRPA. Studying the functional impact of changes in *Laverania* genomes will tell us about the evolutionary origins of one of the deadliest human pathogens, and may shed light on potential targets for vaccine development.

[1]University of Maryland School of Medicine, Baltimore, MD, United States, [2]University of Sciences, Techniques and Technologies of Bamako, Bamako, Mali, [3]Duke Global Health Institute, Duke University, Durham, NC, United States

The *var* gene family encodes *Plasmodium falciparum* erythrocyte membrane protein-1 (PfEMP1) antigens. These proteins locate to the surface of infected erythrocytes and play a critical role in immune evasion. Each *P. falciparum* genome includes 40-60 *var* genes, yet each parasitized erythrocyte displays only one PfEMP1. Studies of *var* expression using non-leukocyte-depleted blood are challenging due to the predominance of host genetic material and lack of *var* reference sequences to guide read recruitment and assembly. To address these barriers, we compared the following mRNA library preparation and *var* transcript enrichment methods to generate assembled *var* transcripts using RNA extracted from whole peripheral blood samples: (1) polyA selection, (2) depletion of globin transcripts and rRNA, (3) both methods combined, and (4) a *var* read capture array, with capture probes based on >1,000 full-length *var* gene sequences. cDNA was generated via reverse transcription and libraries were sequenced using an Illumina platform. To identify *var* gene reads from methods 1-3, we performed *in silico* read capture to identify reads that mapped to any of the *vars* from 3D7, *var* sequences from the VarDom database or >1,000 new *var* sequences. Using 15 samples collected from Malian children with severe or uncomplicated malaria infections, methods were compared based on the percentage of reads mapped to the human and *P. falciparum* genomes and the proportion of *var* reads in the dataset. To identify the best preparation method for assembling *var* transcripts, the completeness and length of assembled *var* transcripts was compared. *De novo* transcript assemblies were generated and *var*s as long as 10,000 bp were identified. To determine the sensitivity of these methods, we used 11 of the samples for which the *var* repertoire is known, and compared the *de novo var* transcripts to the known *var* repertoires as positive controls. The results of this analysis will facilitate *var* expression comparative analyses in severe malaria, uncomplicated malaria and asymptomatic parasitemia to illuminate if *var* expression is associated with different malaria syndromes.

EXTREME DIVERSITY AND POPULATION STRUCTURE OF *VAR* GENES CAN EXPLAIN WHY IMMUNITY TO THE BLOOD STAGES OF *PLASMODIUM FALCIPARUM* IS NON-STERILIZING

Shazia Ruybal-Pesántez[1], Kathryn E. Tiedje[1], Gerry Tonkin-Hill[2], Shai Pilosof[3], Abraham R. Oduro[4], Michael F. Duffy[1], Kwadwo A. Koram[5], Mercedes Pascual[3], Karen P. Day[1]

[1]University of Melbourne, Melbourne, Australia, [2]Walter and Eliza Hall Institute, Melbourne, Australia, [3]University of Chicago, Chicago, IL, United States, [4]Navrongo Health Research Centre, Navrongo, Ghana, [5]Noguchi Memorial Institute for Medical Research, Legon, Ghana

*Pf*EMP1 is encoded by the *var* multi-gene family and is a major target of naturally acquired immunity. Variation in *Pf*EMP1 underlies parasite fitness, measured as the ability to evade the host immune response and establish a chronic infection to optimize transmission. We investigated the extent of *var* sequence diversity and population structure in the asymptomatic *P. falciparum* reservoir in an area with seasonal transmission in Bongo District (BD), Ghana. We sampled individuals across all ages with asymptomatic *P. falciparum* infections (both microscopic and, for the first time, submicroscopic infections) to examine the entire parasite reservoir. With the aim to define the transmission dynamics of *P. falciparum* through the lens of *var* genomics, we set out to describe seasonal and age-specific patterns of *var* diversity at the *var* type and repertoire level, within-host infection complexity, temporal *var* dynamics, and population structure. Our analysis of 1,099 *P. falciparum* isolates across two transmission seasons revealed 42,399 *var* types circulating in the population. Strikingly, this extensive diversity was uniquely structured into *var* repertoires that had minimal overlap regardless of season and infection complexity. Through the lens of *var* genes, we explain several key epidemiological features of *P. falciparum* malaria in endemic areas and demonstrate that the transmission system in BD is extremely complex. Despite this complexity, three key features of the molecular epidemiology emerge: (i) extremely high *var* sequence diversity, (ii) limited overlap of *var* repertoires in both seasons, and (iii) rapid turnover of repertoires but maintenance of certain *var* types between seasons. The absence of related parasites was demonstrated by pairwise type sharing and most isolate repertoires shared <10% of their *var* types. Using computational experiments, this highly diverse parasite population with essentially non-overlapping *var* repertoires was shown to explain age-specific patterns of immunity and the epidemiology of *P. falciparum* malaria in high transmission areas.

MALARIA AND MARITIME TRAFFIC ON THE COLOMBIAN PACIFIC COAST

Aimee R. Taylor[1], Diego F. Echevarry[2], Timothy J. Anderson[3], Daniel E. Neafsey[1], Caroline O. Buckee[1]

[1]Harvard T.H. Chan School of Public Health, Boston, MA, United States, [2]Purdue University, West Lafayette, IN, United States, [3]Texas Biomedical Research Institute, San Antonio, TX, United States

Despite global gains in malaria control since 2010 and relatively low incidence compared with other regions worldwide, malaria cases in Colombia doubled between 2015 and 2016, with over 100,000 estimated cases in 2016. As in many regions nearing elimination, malaria transmission is very heterogeneous in Colombia, with a main hotspot of transmission in Choco close to the pacific coast. Given this heterogeneity, it is critical to understand the contribution of human mobility to parasite dispersal, and in particular the importation of parasites into low transmission settings that are susceptible to outbreaks. To explore human drivers of parasite dispersal in Colombia, we have compared measures of human and parasite connectivity between sites on the Colombian pacific coast. Specifically, we compare connectivity between *Plasmodium falciparum* parasite populations using genetic measures of relatedness based on identity by descent, a fundamental population genetic measure linking ancestry to patterns due to recombination that is sensitive to recent demographic events. We then compared measures of parasite connectivity to measures of human connectivity based on maritime traffic and road networks. We find that genetic measures of parasite relatedness are associated with measures of maritime traffic, suggesting travel via boat plays a substantial role in the dispersal of parasites in the region. This finding generates hypotheses about outbreaks across the wider region of South America, and could lead to malaria elimination policies preventing the spread of parasites via maritime routes.

EXPLORATION OF *PLASMODIUM VIVAX* TRANSMISSION AND RECURRENT INFECTIONS IN THE PERUVIAN AMAZON

Annie N. Cowell[1], **Hugo O. Valdivia**[2], Danett K. Bishop[2], Elizabeth A. Winzeler[1]

[1]University of California, San Diego, CA, United States, [2]U.S. Naval Medical Research Unit 6, Lima, Peru

Plasmodium vivax is responsible for more than 75% of all malaria cases in the Americas constituting an important public health threat. Efforts against vivax malaria have been challenged by its ability to generate long lasting dormant liver parasites that can become active weeks or months after the initial infection. We explored *P. vivax* whole genome sequences obtained from 46 patients residing in three villages of the Peruvian Amazon and demonstrated a novel method for distinguishing homologous relapses from recurrent infections. We obtained 69 high quality *P. vivax* whole genome sequences directly from patient samples by selective whole genome amplification (SWGA). Sequence comparisons resulted in 24,571 high quality single nucleotide polymorphisms in the core *P. vivax* genome. These SNPs were mostly located in regions with high SNP density on chromosomes 3, 6, 10 and 13 that covered virulence factors such as the plasmodium interspersed repeat (pir) gene family, merozoite surface protein 8 (msp8), variant interspersed repeat 21 (vir21), and a hypothetical protein located on chromosome 6. Genomic information allowed us to estimate five *P. vivax* subpopulations and evidence of a highly heterogeneous ancestry of some of the isolates. Pairwise comparison of recurrent infections and identity by descent analysis allowed us to differentiate 10 homologous relapses and 3 potential heterologous relapses with highly related parasites from the rest of the samples. Our study shows that Whole genome sequencing (WGS) is a high-resolution tool for distinguishing relapses from reinfections with increased sensitivity, while also providing information about drug resistance and parasite population genetics.

2054

GLYBURIDE, A NLRP3 INHIBITOR REDUCES INFLAMMATORY RESPONSE AND IMMUNOPATHOLOGY IN *LEISHMANIA BRAZILIENSIS* INFECTION

Augusto M. Carvalho[1], Fernanda Novais[2], Camila I. De Oliveira[3], Lucas P. Carvalho[1], Phillip Scott[2], Edgar M. Carvalho[1]

[1]Federal University of Bahia, Salvador, Brazil, [2]University of Pennsylvania, Philadelphia, PA, United States, [3]Instituto Gonçalo Moniz, FIOCRUZ, Salvador, Brazil

Cutaneous leishmaniasis (CL) caused by *Leishmania braziliensis* is characterized by an exaggerated Th1 immune response and peripheral blood mononuclear cells (PBMC) from CL patients secrete high levels of TNF and IFN-gamma that contributes for the control of parasite multiplication but also is associated with tissue damage and ulcer formation. NLRP3 Inflammasome is an intracellular protein complex which be activated by danger-associated molecular patterns, promoting activation of caspase 1 and release of IL-1β. Both NLRP3 inflammasome activation and IL-1β have been linked with disease severity in leishmaniasis. Glyburide is a ATP-sensitive K^+channels inhibitor used for the treatment of type 2 diabetes. Furthermore, glyburide have anti-inflammatory effect specially by prevention the formation of the NLRP3 inflammasome. In the present work we investigated the ability of glyburide to modulate the *in vitro* inflammatory response in CL patients. PBMC and skin lesions biopsies from CL patients were obtained and cultured with soluble *Leishmania* antigen (SLA) in the presence or absence of glyburide and cytokines levels were evaluated by ELISA. The levels of *Leishmania*-specific IL-1β, IL-17 and TNF produced by PBMC from CL patients significantly decreased after *in vitro* treatment with glyburide, without toxic effects to host cells. Biopsies were divided into two, with one half acting as a control, and the other treated with glyburide. While untreated skin lesion biopsies produced high levels of IL-1β, IL-17 and TNF, treatment with glyburide significantly decreased the release of these cytokines in culture. Moreover, levels of IFN-gamma, IL-6 and IL-10 did not change. A positive correlation among IL-1β levels in biopsies and lesion size was found, and this association was lacked after treatment with glyburide. Leishmanicidal effect of glyburide against *L. braziliensis* promastigotes and intracellular amastigotes was not found. Our data pointed out that glyburide reduces inflammatory cytokines in *L. braziliensis* infection and should be considered as adjuvant therapy for CL.

TYPE I INTERFERONS SUPPRESSES ANTI-PARASITIC $CD4^+$T CELL RESPONSES IN VISCERAL LEISHMANIASIS

Rajiv Kumar[1], Patrick Bunn[2], Fabian Rivera[2], Neetu Singh[1], Shyam Sundar[1], Christian Engwerda[2]

[1]Banaras Hindu University, Varanasi, India, [2]QIMR Berghofer Medical Research Institute, Brisbane, Australia

Many pathogens, including viruses, bacteria, and protozoan parasites, suppress cell mediated immune responses through activation of type I Interferon (IFN-1) signalling. However, the role of IFN-1 during *Leishmania donovani* infection causing visceral leishmaniasis (VL) is not well known. Here we report that IFN-1 plays an important role in the pathogenesis of VL by impairing parasite clearance and suppressing pro-inflammatory cytokine production. Mice lacking type-1 IFN signalling (B6.IFNαR1$^{-/-}$ mice) and wild type (WT) C57BL/6 mice were infected intra-venously with $2x10^7$ *L. donovani* amastigotes. Parasite burden was measured at day 14, 28 and 56 post infection. To further study the impact of IFN-I on the immune response during experimental VL, we next analyzed serum cytokine levels in naive and infected WT and IFNαR1$^{-/-}$ mice. Intracellular cytokine staining and flow cytometry was performed to detect the $CD4^+$ T cell-derived IFN-γ production. Peripheral blood mononuclear cells (PBMCs) from VL patients (before and after treatment) and endemic healthy controls were also collected to measure mRNA encoding IFN-1 related genes and a whole blood assay was employed to measure the antigen specific immune response after IFN-1 signalling blockade. B6.IFNαR1$^{-/-}$ mice showed enhanced pro-inflammatory cytokine production and better control of parasite burden in liver as well as spleen, compared to wild type C57BL/6 mice. IFN-1 signalling suppressed $CD4^+$ T cell-derived IFN-γ production and prevented Th1 response from controlling parasite replication. Studies in VL patients supported these findings and showed enhanced accumulation of mRNA encoding type I IFN signature genes in PBMCs that were reduced following successful drug therapy. Critically, we also showed, using a whole blood assay, that blockade of type-1 IFN signalling enhanced antigen specific IFN-γ production, and that this response was HLA-II restricted. Together, these results identify the type-1 IFN signalling pathways as a potential therapeutic target to treat VL by enhancing anti-parasitic $CD4^+$ T cell responses.

ROLE OF EXOSOMAL MICRORNAS IN SHAPING PROTECTIVE IMMUNITY INDUCED BY LIVE ATTENUATED *LEISHMANIA* PARASITE VACCINES

Sreenivas Gannavaram, Maysum Chaudhri, Parna Bhattacharya, Hira L Nakhasi

US Food and Drug Administration, Silver Spring, MD, United States

In our efforts for the development of an effective vaccine against visceral leishmaniasis, we have reported extensively on the immunogenicity of live attenuated Centrin gene deleted *Leishmania* mutants that are in use in ongoing preclinical studies. However, there is a need to develop biomarkers at early stages of vaccination in a human challenge model to measure vaccine efficacy with live attenuated parasites. Our *ex vivo* infection studies with human PBMCs obtained from U.S. blood donors demonstrated that the early gene expression profiles of several miRNAs (miRs) in virulent and attenuated *Leishmania* infections differ significantly. Towards identifying early biomarkers induced by infection with live attenuated *Leishmania* parasite, we performed *in vitro* infection of murine dendritic cells (DCs) with virulent and attenuated strains of *Leishmania* parasites. The exosomes from the infected DCs were isolated and the miR composition of the exosomes was determined by RNA sequencing. Results showed that several miRs were highly enriched in the exosomes derived from attenuated *Leishmania* infection compared to exosomes from uninfected or virulent infections. Based on the enrichment in attenuated *Leishmania* infection and the previously known roles in orchestrating host immunity, we have selected to investigate the expression of miR-Let-7e, miR-501, miR-16 and miR-361 in murine and *ex vivo* human infection experiments. qRT-PCR assays from the exosomes derived from human macrophages infected with virulent or live attenuated *Leishmania* parasites showed similar enrichment of miRs, as was observed in murine DC infection studies. Further analysis of the role of such miRs in immunity is being currently studied. Taken together, our data suggests that exosomal miRs could be used as biomarkers of protection in anti-leishmanial vaccines.

CHAGAS DISEASE CARDIOMYOPATHY: ASSOCIATION WITH IL-17 AND IL-18 GENETIC POLYMORPHISMS

Alexandra Gomes dos Santos[1], Daiane Tomomi Ferreira[2], Jamile Oliveira[1], Claudia Silva Oliveira[1], Edimar Bocchi[3], Cristina Novaes[4], Fatima Cruz[3], Noemia Carvalho[1], Paula Keiko Sato[2], Vera Lucia Freitas[2], Maria Aparecida Shikanai-Yasuda[1]

[1]Departamento de Doenças Infecciosas e Parasitárias, Faculdade de Medicina, University of São Paulo, Sao Paulo, Brazil, [2]Laboratory of Immunology, Hospital das Clínicas, Faculdade de Medicina, University of São Paulo, Sao Paulo, Brazil, [3]Heart Institute, Hospital das Clínicas, Faculdade de Medicina, University of São Paulo, Sao Paulo, Brazil, [4]Divisão de Moléstias Infecciosas e Parasitárias, Faculdade de Medicina, University of São Paulo, Sao Paulo, Brazil

Chagas disease is an important health problem in endemic and non-endemic areas on many continents, as consequence of immigration of infected people from Latin America. *Trypanosoma cruzi* infects around 7 million people nowadays. About 30% of chronic Chagas disease patients develop inflammatory cardiopathy. We investigated the association between the polymorphisms on inflammatory cytokine genes and the presence of cardiopathy in these patients. We analyzed 212 Chagas disease patients and 90 healthy controls. Trypanosomiasis diagnosis was defined by two positive tests (ELISA, Indirect Immunofluorescence or Hemagglutination). Patients were initially classified in clinical forms: Indeterminate form (without cardiopathy or digestive involvement), Cardiac, Digestive and Cardiac + Digestive forms. Additionally, they were analyzed according to the presence of cardiopathy. DNA was extracted by guanidine hydrochloride or by DTAB/CTAB (dodecyl trimethylammonium bromide/ cetyl trimethylammonium bromide) technique. Polymorphisms on IL1 511 G/A (rs1143627), IL6 174 C/G (rs1800795), IL17 152 G/A (rs2275913), IL18 137 C/G (rs187238), IL18 607 G/T (rs1946518) were analyzed by Real Time-PCR. The population was in Hardy-Weinberg equilibrium. There were no differences in genotypic and allelic frequencies between patients and healthy controls. Logistic regression analyses showed that IL17 152 AA and IL18 607 TT genotypes have protective effect on Chagas disease cardiopathy (p= 0.032, OR= 0.229, IC= 0.059-0.883 and p=0.026, OR=0.264, IC=0.081-0.854, respectively). In contrast to previous analyses, our study suggests a role of IL17 152 G/A and IL18 607 G/T polymorphisms in the presence of cardiopathy in chronic Chagas disease.

The cutaneous leishmaniasis (CL) caused by *L. braziliensis* is characterized by a well limited ulcer with raised borders. As only a few parasites are found at the lesion site, emphasis has been giving to the role of both CD4 and CD8 T cells exaggerated immune response in the pathogenesis of the disease. However cutaneous ulcers are documented in patients with a poor type 1 immune response as observed in patients co-infected with HIV and *L. braziliensis* and is also observed in CL patients with a negative delayed type hypersensitivity to the leishmania skin test (LST). Here we compare the immune response in CL patients with a negative and positive LST and correlate the immunologic response with pathology and response to therapy. Participants include 13 patients with CL with LST$^-$ (cases) and 26 CL patients with LST$^+$ (controls). The diagnosis was performed by the detection of DNA of *L. braziliensis* by PCR. Histopathological findings

were analyzed, cytokine levels were determined by ELISA in supernatants of mononuclear cells stimulated with SLA and the ability of macrophages to kill leishmania was determined by optical microscopy. There was no difference regarding the age, gender and illness duration between the two groups. All patients presented a typical CL ulcer and there was no difference in the size of the lesions in those with LST+ and LST- However while failure to antimony ($Sb^{5)}$ therapy was observed 9 of 13 (69,2%) of the cases it was found in 9 of 26 (34,6%) of controls (P< .05). There was no difference regarding the leishmania killing by macrophages. IFN gamma and TNF levels were lower (P<.01) in those with a negative LST. High levels of IL-1 beta, CXCL-9, and MMP-9 were detected in both groups. While there was no correlation between IFN gamma levels and size of the ulcers, there was a strong correlation between IL-1 beta levels and the size of the ulcers (R=0,78; P<001). In CL while high production of IL-1β is associated with pathology, impairment in Th1 immune response is associated with therapeutic failure.

2059

INSULIN-LIKE GROWTH FACTOR-I AS EFFECTOR ELEMENT OF IL-4 EFFECT LEADING TO SUSCEPTIBILITY TO *LEISHMANIA MAJOR* INFECTION

Hiro Goto[1], Luiza C. Reis[1], Eduardo M. Ramos-Sanchez[1], Fabricio Petitto-Assis[1], Audun H. Nerland[2], Maria Hernandez-Valladares[2], Frode Selheim[2], Lucile M. Floeter-Winter[1]

[1]Universidade de São Paulo, São Paulo, Brazil, [2]University of Bergen, Bergen, Norway

In *Leishmania* infection IGF-I favors the parasite growth inducing an increase in arginase activity in infected macrophages. Since it is known that arginase is activated by IL-4, here we aimed to study the role of intrinsic IGF-I in conjunction with IL-4 in *Leishmania major* promastigote-infected RAW 264.7 cells through silencing *Igf-I* mRNA expression with addition of IL-4 (2ng/ml) in some experiments. After 48 hours *Igf-I* mRNA expression was quantified by Real Time (qPCR), and nitric oxide (*Nos2*) by qPCR and Griess method and, arginase (*Arg1*) by qPCR and arginase activation by urea production, and the parasitism by microscopy. In all groups treated with siRNA we observed a decrease in the arginase mRNA expression and arginase activity in macrophage and parasite, accompanied by a significant decrease in the parasitism from 149 (median) parasites per 100 cells to 93. Upon IL-4 stimulus *Igf-I* mRNA expression was increased as well as the parasitism that reached 171. However in siRNA-treated cells IL-4 stimulus did not induce any increase in *Igf-I* mRNA expression and the parasitism reduced to 87. Upon restoring IGF-I with 50 ng/ml recombinant IGF-I (rIGF-I) after knockdown an increase in the parasite arginase mRNA expression was seen accompanied by an increase in the parasite number to the level similar to the controls and further the effect of IL-4 stimulus was restored. Searching for intracellular signaling elements (by Westernblot) upon siRNA transfection, phosphorylated p44, p38 and Akt proteins were seen decreased affecting phosphatidylinositol-3-kinase (PI3K)/Akt pathway, effects that were reversed by the addition of rIGF-I. Further in *L. major*-infected C57BL6 resistant mice pre-incubation of parasites with rIGF-I that were subcutaneously injected in the footpad turned the infection profile similar to susceptible mice. These results suggest that IGF-I is directly related to expression and activation of arginase mainly on *Leishmania* in infected macrophages leading to increase in the parasitism and we conclude that IGF-I constitutes an effector element of IL-4 involving PI3K/Akt pathway during *L. major* infection.

2060

INVOLVEMENT OF TH17 RESPONSES IN HUMAN VISCERAL LEISHMANIASIS

Om Prakash Singh[1], Nasim Ansari[2], Rajiv Kumar[1], Susanne Nylen[3], Madhukar Rai[1], David Sacks[2], Shyam Sundar[1]

[1]Institute of Medical Sciences, Banaras Hindu University, Varanasi, India, [2]Laboratory of Parasitic Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD, United States, [3]Karolinska Institutet, Department of Microbiology Tumor and Cell Biology, Stockholm, Sweden

Visceral leishmaniasis (VL) is a potentially fatal parasitic disease that impose a huge health problem on the vulnerable population claiming the lives of 0.2- 0.4 million worldwide. Better understandings of disease pathogenesis that dampen the immune response are critical for controlling the disease. We had previously shown the role of IL-27 and IL-21 in differentiation and expansion of antigen-specific IL-10 producing T cells and inhibition of Th17 differentiation in VL patients. Here, we investigated the IL-17 association with protection in human VL. We found elevated mRNA expression of indolamine 3-3-di-oxygenase in VL patients, the enzyme that negatively regulates T-cell effector function during infection. No up-regulation of IL-17 or RORγT mRNA expression in spleens cells and plasma IL-17 levels were detected in active VL, however significantly elevated mRNA levels of both subunits of IL-23 were detected in post treated VL splenic biopsies compared to active patients. IFN-γ or/and IL-10 neutralization does not affect IL-17 levels in whole blood cells of active VL and 6 months cured VL. However, plasma IL-17 and IFN-γ levels were elevated in 6 month cured VL which were further enhanced with SLA stimulation in whole blood. Analysis of Th17/Th1 cytokines response in subjects from a cohort of endemic healthy individuals who were protected against VL showed that IL-17 is strongly associated with protection against VL. These findings were further supported by enhance parasite clearance with recombinant IL-17 (rhIL-17) and rhIFN-γ by inducing TNF-α mRNA and down regulating IL-10 in monocyte derived macrophages infected with *L. donovani* amastigote.

BUBBLE CONTINUOUS POSITIVE AIRWAY PRESSURE FOR CHILDREN WITH SEVERE PNEUMONIA AND SEVERE MALNUTRITION, HUMAN IMMUNODEFICIENCY VIRUS INFECTION OR EXPOSURE, OR SEVERE HYPOXEMIA IN MALAWI: AN OPEN LABEL RANDOMIZED CONTROLLED TRIAL

Eric D. McCollum[1], Tisungane Mvalo[2], Andrew G. Smith[3], Michelle Eckerle[4], Davie Kondowe[5], Norman Lufesi[6], Alfred Chalira[6], Dhananjay Vaidya[1], Innocent Mofolo[2], Mina C. Hosseinipour[2]

[1]Johns Hopkins School of Medicine, Baltimore, MD, United States, [2]University of North Carolina Chapel Hill, Chapel Hill, NC, United States, [3]University of Utah School of Medicine, Salt Lake City, UT, United States, [4]University of Cincinnati College of Medicine, Cincinnati, OH, United States, [5]University of North Carolina Project, Lilongwe, Malawi, [6]Malawi Ministry of Heath, Lilongwe, Malawi

Pneumonia is a leading cause of death among African children. Those children with the co-morbidities of severe malnutrition or human immunodeficiency virus (HIV) infection or exposure, or severe hypoxemia are at the highest risk of pneumonia mortality despite standard care with antibiotics and low-flow oxygen. Bubble continuous positive airway pressure (bCPAP) is a lower-cost non-invasive ventilation modality that may improve child pneumonia survival. This open label randomized controlled trial was conducted at Salima District Hospital, Malawi. We planned to enroll 900 children 1-59 months old with severe pneumonia and either severe malnutrition, HIV infection or exposure, or an oxygen saturation <90%. Children were randomly assigned 1:1 to low-flow nasal cannula oxygen (0.5 to 2 L/min) or bCPAP (5 to 8cm H_20). The primary outcome was hospital death. Safety analyses were done per protocol and primary analyses by intention to treat. The data safety and monitoring board stopped the trial early (ClinicalTrials.gov NCT02484183). We recruited 646 eligible children. A total of 324 children (50.2%) were randomized to low-flow oxygen and 322 (49.8%) to bCPAP. Overall 88 children died in the hospital (13.6%), 35 were allocated to low-flow oxygen (10.8%) and 53 to bCPAP (16.4%). Children receiving bCPAP had significantly higher rates of death compared to low-flow oxygen recipients (relative risk 1.52 (95% confidence interval, 1.02, 2.25, p=0.039). bCPAP significantly increased

hospital mortality among high-risk Malawian children with severe pneumonia, compared to low-flow oxygen. Based on these results bCPAP is not recommended for similar pediatric pneumonia populations.

2062

OUTCOME OF POST TRIAL IMPLEMENTATION OF BUBBLE CPAP IN TREATING CHILDHOOD SEVERE PNEUMONIA AND HYPOXEMIA IN BANGLADESH

Mohammod J. Chisti, KM Shahunja, Abu S. Shahid, Tahmeed Ahmed

International Centre for Diarrhoeal Disease Research, Bangladesh (icddr,b), Dhaka, Bangladesh

Despite of World Health Organization (WHO) recommended low flow (LF) oxygen therapy, antibiotics, and other standard care; deaths from childhood severe pneumonia exceed 10% in many hospitals of developing countries. A randomized clinical trial (RCT) conducted in icddr,b, Bangladesh from August 2011 to July 2013 showed bubble CPAP oxygen therapy was associated with significant reduction of deaths (4% vs. 15%, p=0.022) in treating childhood severe pneumonia and hypoxemia compared to those received LF therapy. Subsequently bubble CPAP was incorporated as the part of standard of care in treating such children. We evaluated outcome of post trial implementation of bubble CPAP in these children between August 2013 and December 2017. Children under-five with WHO defined severe pneumonia and hypoxemia were included in our analysis. Children who presented with features of respiratory failure (such as gasping respiration) or congenital heart disease on admission were not eligible for the bubble CPAP oxygen therapy. A total of 4101 children were admitted with pneumonia having different severity during the study period. Among them 2850 children had severe pneumonia, 1183 (29%) had hypoxemia, 742 (18%) were eligible for bubble CPAP oxygen therapy but the rest of the hypoxemic children (411) were not eligible to receive bubble CPAP therapy. The median age of the children who received bubble CPAP was 7.3 (IQR: 4.2, 11.4) months, 294 (40%) of them had severe acute malnutrition, 118 (16%) severe sepsis, 183 (25%) convulsion, 70 (9%) bacteremia, 72 (10%) abdominal distension, but none of them developed nasal bleeding or pneumothorax. A total of 211/4101 (5%) children died of pneumonia in all categories, 206/2850 (7%) died of severe pneumonia, and 42 (5.7%) died who received bubble CPAP. However, the pre-trial mortality was 21% in children with same eligibility criteria of bubble CPAP therapy. Thus, the outcome of implementation of bubble CPAP in treating childhood severe pneumonia and hypoxemia is consistent with the RCT in Bangladesh and has high potential to implement it in other developing countries having high mortality in childhood pneumonia.

2063

RESULTS FROM A RECENTLY CONCLUDED COMMUNITY BASED RANDOMIZED NON-INFERIORITY TRIAL OF AMOXICILLIN VERSUS PLACEBO IN FAST BREATHING PNEUMONIA IN LOW INCOME COMMUNITIES IN PAKISTAN

Fyezah Jehan, Imran Nisar, Benazir Baloch, Salima Kerai, Najeeb-ur- Rahman, Arjumand Rizvi, Nick Brown, Anita K. Zaidi

Aga Khan University, Karachi, Pakistan

World Health Organization (WHO) recommends use of amoxicillin in managing fast breathing pneumonia, diagnosed on clinical signs that classify children based on respiratory rates. Given non-specificity of case definition, there is equipoise regarding use of antibiotics in management of fast breathing pneumonia. We conducted a double blind randomized placebo controlled non inferiority trial with parallel assignment in high pneumonia mortality slums of Karachi, Pakistan. Children 2-59 months with fast breathing without any WHO defined danger signs and seeking care at primary health centre were randomized to receive either three days of placebo or amoxicillin. Primary outcome was cumulative treatment failure (new clinical sign based on pre-set definition indicating illness progression or mortality) on day 0, 1, 2 or 3 of therapy. Sample size was 4000 children assuming a treatment failure rate of 3.5% in amoxicillin arm, with one sided alpha of 0.05, power of 90%, non-inferiority margin of 1.75% and an expected 5% lost to follow-up/non per protocol. From November 2014 to November 2017, 98,334 children were triaged, 53,770 (54.7%) presented with cough or difficulty breathing. 7,887 (14.7%) met inclusion criteria, and 4003 (89.3 %) of them were randomized. In placebo arm, 2000 were randomized and 1927 were per protocol (96%), with 94 (4.9%) treatment failures and 40 (2.2%) relapses. In Amoxicillin arm, 2003 were randomized with 1929 per protocol (96%) with 51 (2.6%) treatment failures and 58 (3.1%) relapses. The difference of absolute treatment failure rates between two groups was 2.23% with one sided 95% CI (1.23-3.24). Based on preset non inferiority criteria, we failed to conclude non inferiority of placebo to amoxicillin. However, we found a high number needed to treat, 1 in 44 to prevent a fatal or non-fatal adverse event. Also, 90% of those who did receive antibiotics did not experience any clinical worsening. Findings are generalizable to low HIV and malaria setting with Hib/Pneumococcal vaccines in their national immunization plan and have implications for readdressing the respiratory rate cutoffs for defining fast breathing pneumonia.

2064

PROGNOSTIC BIOMARKERS IN UGANDAN CHILDREN WITH RESPIRATORY SYNCYTIAL VIRUS RESPIRATORY TRACT INFECTION

Julia Sawatzky[1], Andrea L. Conroy[2], Sophie Namasopo[3], Robert O. Opoka[4], Michael T. Hawkes[1]

[1]University of Alberta, Edmonton, AB, Canada, [2]Indiana University School of Medicine, Indianapolis, IN, United States, [3]Jinja Regional Referral Hospital, Jinja, Uganda, [4]Mulago Hospital and Makerere University, Kampala, Uganda

Respiratory Syncytial Virus (RSV) is the leading viral cause of pediatric pneumonia worldwide. Optimizing outcomes from RSV pneumonia requires a determination of severity that, in resource-limited settings, is often based on clinical assessment alone. Here we describe levels of biomarkers of systemic inflammation, C-Reactive Protein (CRP), Chitinase-3-Like Protein 1 (CHI3L1) and Lipocalin-2 (LCN2), and a marker of pneumocyte injury, Surfactant Protein D (SP-D), and clinical outcomes of children hospitalized with RSV pneumonia in Uganda, as well as controls with rhinovirus and pneumococcus. 58 children hospitalized with clinical pneumonia (hypoxemia, tachypnea and/or chest in-drawing) were included. We compared 37 patients in whom RSV was detected in the NP swab, 10 control patients with rhinovirus, and 11 control patients with pneumococcal pneumonia. Diagnostically, patients in the RSV group had significantly lower levels of CHI3L1 and CRP than the pneumococcal group ($p<0.05$ for both comparisons) and similar levels to the rhinovirus group. In terms of prognosis within the RSV group, higher levels of CHI3L1 were associated with higher composite clinical severity scores at admission (RISC), $r= 0.41$, $p =0.019$, and predicted prolonged time to resolution of tachypnea and tachycardia, time to wean oxygen, and time to sit ($p<0.05$ for all comparisons). Higher levels of LCN2 were associated with prolonged time to resolution of tachypnea, tachycardia and fever, and time to feed. Higher levels of CRP were associated with prolonged time to resolution of tachypnea, tachycardia, and fever. Higher admission levels of CHI3L1, LCN2, CRP, and SP-D were predictive of a higher total volume of oxygen administered during hospitalization ($p<0.05$ for all comparisons). Of note, CHI3L1 and LCN2 appear to predict normalization of respiratory rate and supplemental oxygen requirement more accurately than CRP, the most widely-used host inflammatory biomarker in clinical practice. Our findings suggest that CHI3L1 and LCN2 may be clinically informative biomarkers of childhood RSV respiratory tract infection in low-resource settings.

RISK OF TUBERCULOSIS IN HOSPITAL ENVIRONMENTS IN A COUNTRY WITH HIGH ENDEMICITY

Antonio M. Quispe[1], Alfredo Arróspide Medina[2], Mirtha Valladares Fernández[2], Cleopatra Huapaya Pizarro[2], Joshi Acosta Barriga[1]

[1]Instituto de Evaluación de Tecnologías de Salud e Investigación, EsSalud, Lima, Peru, [2]Gerencia Central de Prestaciones de Salud, EsSalud, Lima, Peru

Health workers are one of the occupational groups with the highest risk of becoming infected with tuberculosis (TB) due to their regular occupational exposure. This study was aimed to estimate the TB risk at the hospital environments with the highest incidences of TB within the Peruvian Social Security System (EsSalud), and its associated factors. Using a cross-sectional study design, we estimated the TB risk at each of the hospital environments destined to provide care to the TB patients at the hospitals with the highest incidence of TB (upper quartile) across EsSalud regional health networks. We quantified the TB risk using the Wells-Riley airborne model and either by the CO2 concentration or the flow rate techniques, based on the feasibility for the total closure of the environment. Then, we assessed the characteristics of the environments, hospitals and health networks as associated factors by using a multilevel mixed-effects model. We assessed 480 environments, 22 (25%) hospitals (22±5 environments/hospital) and 12 (46%) regional health networks and estimated an average TB risk of 42% (95% confidence interval [CI]: 39% -45%). At the bivariate analysis, we found that the TB risk was significantly lower in the regions of Lambayeque (vs. Loreto, Huánuco, Tacna, and Arequipa) and Lima (vs. Loreto), in the TB Program environments (vs. emergencies, hospitalization, and doctor's offices), in those with natural ventilation (vs. air conditioning), and in those with the lower ratio of windows to doors, but significantly higher at level III hospitals (vs. levels I and II). However, in the multivariate analysis, we identified as associated factors the type of environment (TB Program [Reference]] vs. doctor's offices [β_1=12, IC95%:3-22], hospitalization [β_2=20:11-29] and emergencies [β_3=25: 16-34]), and the type of ventilation (natural [Ref.] vs. air conditioning [β_4=17:6-21]). To sum up, the TB risk at the environments from the hospitals with the highest incidence of TB at EsSalud is high and highly variable, being lower at the TB Program facilities and the naturally ventilated environments

DIFFERENCES IN CLINICAL SEVERITY OF MONO AND MULTIPLE RESPIRATORY VIRAL INFECTIONS IN HOSPITALIZED CHILDREN IN NHA TRANG, VIETNAM

Benjamin M. Althouse[1], Stefan Flasche[2], Michiko Toizumi[3], Hien-Anh Thi Nguyen[4], Hien Minh Vo[5], Minh Nhat Le[4], Masahiro Hashizume[3], Koya Ariyoshi[3], Dang Duc-Anh[4], Gail L. Rodgers[6], Keith P. Klugman[6], Hao Hu[1], Lay-Myint Yoshida[3]

[1]Institute for Disease Modeling, Bellevue, WA, United States, [2]London School of Hygiene & Tropical Medicine, London, United Kingdom, [3]Nagasaki University, Nagasaki, Japan, [4]National Institute of Hygiene and Epidemiology, Hanoi, Vietnam, [5]Khanh Hoa General Hospital, Nha Trang, Vietnam, [6]Bill & Melinda Gates Foundation, Seattle, WA, United States

It is a standing question whether clinical severity of an infection varies by pathogens or by infection with multiple pathogens. Using hospital-based surveillance in children, we investigate the range of clinical severity for patients singly, multiply and not infected with a group of 12 commonly circulating viruses in Nha Trang, Vietnam. We find no difference in severity between 0-, 1-, and 2-concurrent viruses and little differences in severity between specific viruses. We find that concurrent infection with 3 or more viruses was associated with nearly a 3-fold increase in the odds of being a severe case, as well as detection of Human metapneumovirus and respiratory syncytial virus -- either as a monoinfecton or as part of a coinfection -- is associated with increased risk of being severe. Finally, we find infection with adenovirus to be consistently associated with lower risk of severity. Clinically, based on the results here, if Human metapneumovirus and respiratory syncytial virus virus is suspected, PCR testing for confirmatory diagnosis and for detection of multiple coinfecting viruses would be fruitful to assess the probability of whether the patient's disease course is going to be severe.

2067

LOWER RESPIRATORY INFECTIONS ARE THE LEADING INFECTIOUS CAUSE OF DEATH GLOBALLY: INCIDENCE, HOSPITALIZATIONS, AND MORTALITY IN THE GLOBAL BURDEN OF DISEASE STUDY 2017

Christopher Troeger, **Brigette Blacker**, Ibrahim Khalil, Stephanie R. Zimsen, Jonathan Brown, Nicholas Kassebaum, Simon I. Hay, Robert C. Reiner

Institute for Health Metrics and Evaluation, Seattle, WA, United States

Lower respiratory infections are the leading infectious cause of death globally, responsible for more deaths than tuberculosis and HIV/AIDS, combined. The Global Burden of Disease study 2017 (GBD 2017) is a systematic, scientific effort to quantify health for all ages, both sexes, every geography, and from 1980-2017. In this presentation we will share methodology and updated results for lower respiratory infections (LRIs) in GBD 2017, focusing on deaths, incidence, and hospitalizations. Deaths, incidence, and hospitalizations were modeled separately using vital registration, verbal autopsy, survey, health records, and scientific literature data and these regression models were strengthened by covariates and by hierarchical space-time trends. Overall, lower respiratory infections were the third leading cause of disability-adjusted life years (DALYs) globally in 2017, responsible for 91,844,000 DALYs, 2,558,200 deaths, and 336,461,000 incident episodes. The number of DALYs, deaths, and episodes has been increasing since 2000 (about 30% overall increase during this time), but the rate has remained about the same for episodes, and the mortality rate has decreased dramatically (mortality decreased 28% during this time). In 2017, we estimated that there were 32,990,000 hospitalizations due to LRIs. Most of these hospitalizations occurred among adults over age 65 (11,490,000 hospitalizations), accounting for a rate of 18.2 LRI hospitalizations per 1,000 people. The next highest rate of hospitalization due to LRIs was among children under 1 year (9.2 per 1,000) with lower rates in the 15 to 64 years age groups. Overall, about 10% of LRI episodes were hospitalized globally with the highest proportion hospitalized among elderly adults over 65 years (13.8%). The Global Burden of Disease study provides a timely, comprehensive, and detailed picture of the health loss associated with LRI and provides public health experts, policy makers, and health officials with evidence for decision making and a roadmap for reducing the burden of the disease.

DRY SEASON *P. FALCIPARUM* RESERVOIR

Carolina Andrade[1], Hannah Fleckenstein[1], Safiatou Doumbo[2], Julia Hibbert[1], Richard Thomson-Luque[1], Carrie Anderson[1], Nathalia F. Lima[1], Shanping Li[3], Christine Hopp[3], Didier Doumtabe[2], Nuno Osorio[4], Dan Sturdevant[5], Craig Martens[5], Kassoum Kayentao[2], Ogobara K. Doumbo[2], Thomas Lavstsen[6], Aissata Ongoiba[2], Boubacar Traore[2], Peter D. Crompton[3], **Silvia Portugal**[1]

[1]Heidelberg University Hospital, Heidelberg, Germany, [2]Mali International Center of Excellence in Research, Bamako, Mali, [3]National Institute of Allergy and Infectious Diseases, National Institutes of Health, Rockville, MD, United States, [4]School of Health Sciences, University of Minho, Braga, Portugal, [5]Rocky Mountain Laboratory Research Technologies Section, National Institutes of Health, Hamilton, MT, United States, [6]University of Copenhagen, Copenhagen, Denmark

Dependent on Anopheles mosquito for transmission, *P. falciparum* faces a challenge during the dry season in the regions where rain seasonality limits vector availability for several months. While malaria cases are restricted to the wet season, clinically silent infections can persist through

the dry season and are an important reservoir for transmission. Chronic asymptomatic *P. falciparum* infections allow transmission to resume with every rainy season, and predict decreased clinical malaria risk during the next malaria season. However, asymptomatically infected Malian children appear to maintain only minimal immune activation during this time and *P. falciparum*-specific antibodies decline similarly in children who do or do not harbour asymptomatic *P. falciparum* infections during the dry season. We hypothesized that newly transmitted parasites are more virulent and induce stronger immune responses than parasites that persist during long periods of asexual replication in blood. We thus compared whole genome transcription of *P. falciparum* parasites maintained during the dry season, with parasites collected from children during acute febrile malaria episodes. Our data indicates that *P. falciparum* modulates its transcription during the dry season, while the host immune response seems to be minimally affected, suggesting that the parasite has the ability to adapt to a vector-free environment for long periods of time. *P. falciparum* signaling pathways related with metal ion transport, phospholipid biosynthesis, DNA replication and macromolecular membrane complexes were significantly altered during the dry season leading us to investigate exported proteins and adhesive properties of infected erythrocytes, as well as *P. falciparum* replicative ability during the dry and wet seasons. Understanding how the parasite adapts to a vector-free environment for long periods of time remaining undetectable to the immune system, and how it can restart transmission in the ensuing rainy season will reveal complex interactions between *P. falciparum,* its host, and the environment, and may inform malaria elimination strategies.

TRANSCRIPTOME PROFILING UNRAVELS NOVEL LIGANDS REQUIRED FOR *PLASMODIUM VIVAX* INFECTIONS IN *SAIMIRI* MONKEY - IMPLICATIONS ON *PLASMODIUM VIVAX* INFECTIONS IN AFRICA

Karthigayan Gunalan[1], Juliana M. Sa[1], Roberto R. de Moraes Barros[1], Kishore Kanakabandi[2], Sarah L. Anzick[2], Ramoncito L. Caleon[1], J. Patrick Mershon[1], Craig Martens[2], Thomas E. Wellems[1], Louis H. Miller[1]

[1]National Institutes of Health, Rockville, MD, United States, [2]National Institutes of Health, Hamilton, MT, United States

Plasmodium vivax causes severe disease in humans in Asia and South America. The engagement of *P. vivax* Duffy binding protein 1 (DBP1) with Duffy blood group antigen (Duffy antigen) in the host erythrocytes is important for invasion. Most Africans lack Duffy antigen on the erythrocyte surface and hence *P. vivax* infection in Africa is remarkably rare or completely absent. However, recent cases of *P. vivax* infections have been reported in various parts of Africa in Duffy-negative Africans. This may suggest that *P. vivax* uses alternate invasion pathways to invade Duffy-negative erythrocytes. Evolution of *P. vivax* may, therefore, put Africans at risk of severe disease in the future. To identify the candidate ligands that are crucial for *P. vivax* infection in Africa, we study clinical isolates and in parallel, we use relevant primate models. DBP1, the key ligand for *P. vivax* Salvador I infection binds to *Aotus* monkey erythrocytes but not to *Saimiri* monkey erythrocytes. It is known that DBP1 binds to Duffy-positive erythrocytes but not to Duffy-negative erythrocytes. Thus, studying the difference in the expression of genes in Salvador I parasites from *Saimiri* and *Aotus* monkeys might unravel alternative invasion pathways that might provide insights on *P. vivax* infection in Duffy-negative erythrocytes. We have performed *P. vivax* Salvador I infection in three *Saimiri* and four *Aotus* monkeys. Trophozoites stage parasites were isolated by magnetic separation using MACS columns and allowed to mature to late schizont stage parasites *in vitro*. Next-generation sequencing using Illumina platform was performed to gain insights on the difference between the *P. vivax* transcriptomes in *Saimiri* and *Aotus* infected monkeys. Interestingly three novel genes showed up to a 30-fold increased gene expression in *Saimiri* infection when compared to *Aotus* infection. These proteins may potentially be involved in alternate invasion pathways and need to be examined in Duffy-negative *P. vivax* infection. Currently, we are elucidating the biological significance of these upregulated proteins which may be vital for understanding Duffy-negative *P. vivax* infections in Africa.

2070

CHARACTERIZATION OF *PLASMODIUM VIVAX* GENE EXPRESSION DURING CLINICAL INFECTIONS AND UPON CHLOROQUINE TREATMENT

David Serre

University of Maryland, Baltimore, MD, United States

Studies of gene expression have the potential to provide unique insights on the biology of *P. vivax* parasites. However, due to the lack of continuous *in vitro* propagation system for *P. vivax*, most studies have to rely on patient samples, which complicates molecular investigations due to the polyclonality of most infections, the concurrent presence of different blood-stages (each with their own regulation and responses), and the abundance of host molecules. Here, we show that we can routinely generate robust RNA-seq profiles for blood-stage *P. vivax* parasites using blood from infected patients, without any pre-processing. Gene expression deconvolution analysis of 26 Cambodian patients confirms that most RNA molecules derive from trophozoites and, thus, that the asynchronicity of *P. vivax* infections *in vivo* is unlikely to confound gene expression studies. Despite this overwhelming signal from trophozoites, we show that known gametocyte genes are detectable in most infections, but form two distinct clusters of co-regulated genes (possibly reflecting different transcriptional regulations of male and female gametocytes). We also perform high-throughput sequencing of mRNA from selected genes after RT-PCR amplification and show that, in polyclonal infections, the proportion of parasites committed to gametocytogenesis is similar across clones. Finally, we analyze the changes in parasite gene expression induced by chloroquine treatment and show that, despite a large effect on parasitemia, chloroquine does not alter the gene expression profiles. We hypothesize that chloroquine efficiently clears most *P. vivax* parasites but does not affect trophozoites, leaving the overall patterns of gene expression unscathed. Lastly, we show that RNA-seq analyses of *P. vivax*-infected patient blood can be complemented with single-cell RNA-seq experiments in non-human primates. These experiments enable to rigorously study changes in stage composition and in the regulatory program of each development stage, although the cost and logistical difficulty associated with these experiments might limit their use.

The malaria parasite *Plasmodium falciparum* encounters diverse environments throughout its asexual lifecycle, including high parasite densities during sequestration of trophozoites and schizonts in the microvasculature. High parasite densities in the human host have been associated with severe malaria *in vivo*, while regulation of parasite populations below the fever-inducing threshold has been observed in asymptomatic children in Papua New Guinea. Such disparate behavior suggests a key role for parasite responses to density with respect to disease progression and severity. *In vitro* cultures of high density, asexual *P. falciparum* exhibited aberrant morphology during the late trophozoite and schizont stages. These were arrested development, failure of schizont

maturation and merozoite formation, and hallmarks of cell death such as loss of cell volume, mitochondrial membrane depolarization, and blebbing of the parasite plasma membrane with eventual release of aberrant parasites from infected erythrocytes. Density-dependent cell death was not a consequence of glucose or essential amino acid depletion or excess lactate. A multi-omics analysis was performed to characterize the transcriptomic, metabolic, and lipid profiles within the local environment of *P. falciparum in vitro* cultures at densities corresponding to severe malaria. Metabolic analysis of conditioned medium derived from high-density parasite cultures revealed perturbation of compounds involved in amino acid and carbohydrate metabolism, as well as depletion of glycerophospholipids. Individual omics platforms were integrated using a latent component discriminant analysis (DIABLO), identifying a subset of features that described the effects of density on parasite metabolism and were highly correlated across omics platforms. Gene ontology analysis of features selected by integrated analysis illustrated the relatedness of biological pathways perturbed under high-density conditions. Ultimately, this systems biology approach to characterizing parasite metabolism in high-density environments may highlight potential targets for intervention.

2072

REFINED SUB-STRUCTURE OF *PLASMODIUM FALCIPARUM* POPULATIONS IN SUB-SAHARAN AFRICA AND THE IMPLICATIONS FOR THE EMERGENCE AND SPREAD OF ARTEMISININ RESISTANCE

Edwin Kamau[1], Alfred Amambua-Ngwa[2], Lucas Amenga-Etego[3], Deus Ishengoma[4], Ben Andagalu[5], Abdoulaye A. Djimde[6]

[1]Walter Reed Army Institute of Research, Silver Spring, MD, United States, [2]Medical Research Council, Gambia Unit, Banjul, Gambia, [3]Navrongo Health Research Centre, Navrongo, Ghana, [4]National Institute for Medical Research, Tanga, United Republic of Tanzania, [5]KEMRI/United States Army Medical Research Unit–Kenya, Kisumu-Narobi, Kenya, [6]Malaria Research and Training Centre, Bamako, Mali

In recent years, the emergence of artemisinin drug resistance in SEA has resulted in focused attention to this region because it is feared that resistance might spread to SSA. Recent studies have shown K13 mutations are mostly localized in small geographical area in SEA where they originate independently and have particular genetic background. Some of these mutations have also been identified in SSA parasites, but without the delayed clearance phenotype. NS K13 mutations are undergoing strong evolutionary selection in SEA but not in SSA where mutations originate locally. We evaluated the status of artemisinin resistance in SSA by analyzing the K13 mutations. Data reported here is from 10 countries representing east, west and central African nations with different transmission intensities and are geographically dispersed. More than 1300 Pf samples were whole genome sequenced on Illumina. Additional 315 samples from ACT efficacy studies in Kenya were sequenced on Sanger. Despite the presence of sustained high infection complexity, low linkage disequilibrium and high recombination in the isolates tested, NS K13 mutations were present in low frequencies and none of the WHO validated K13 resistance mutations were present. Population structure analysis revealed presence of distinct east African, Ethiopian and west African parasite populations. Ethiopian isolates were significantly divergent from all other populations including those from neighboring Kenya. Analysis of the drug resistance SNPs resulted in loss of the east-west geographical sub-division of the parasite population structure. There was no evidence of drug resistant gene flow from east to west Africa which is against the popular dogma of east to west gene flow, where resistant parasites migrate from SEA to SSA. K13 mutations in SSA are private, emerge locally, are not under positive pressure, and do not confer artemisinin resistance. The K13 mutations and frequency differ even inside each country, and K13 mutations were present in pre-ACTs parasites. There is no evidence that artemisinin resistant parasites from SEA are likely to flow to SSA, using the east to west route.

LARGE-SCALE USE OF INSECTICIDE-IMPREGNATED 'TINY TARGETS' TO CONTROL TSETSE FLIES IN THE DEMOCRATIC REPUBLIC OF CONGO

Inaki Tirados[1], Fabrice Mpembele[2], Paul Bessell[3], Michelle Stanton[4], Richard Selby[1], Geoffrey Gimonneau[5], Erick M. Miaka[2], Philémon Mansinsa[2], Andrew Hope[1], Catiane Vander Kelen[6], Yves Claeys[6], Rian Snijders[6], Marleen Boelaert[6], Mike J. Lehane[1], Steve J. Torr[1]

[1]Liverpool School of Tropical Medicine, Liverpool, United Kingdom, [2]Programme National de Lutte contre la Trypanosomiase Humaine Africaine, Kinshasa, Democratic Republic of the Congo, [3]Independent consultant, Edinburgh, United Kingdom, [4]Lancaster University, Lancaster, United Kingdom, [5]Cirad, Montpellier, France, [6]Institute of Tropical Medicine, Antwerp, Belgium

In 2014, half of all cases of gambiense-Human African Trypanosomiasis (gHAT) worldwide occurred in the former Bandundu Province of Democratic Republic of Congo (DRC). Efforts to eliminate the disease have been based largely on active screening and treatment of the human population. This approach has halved the incidence of gHAT but additional interventions are required if WHO elimination goals are to be achieved. Control of the vectors - tsetse flies - could accelerate progress but standard methods of controlling the important vectors of gHAT were too costly and complex to implement at scale. Insecticide-treated 'Tiny Targets' have been used successfully to control gHAT in Uganda, Guinea and Chad. We tested whether Tiny Targets could be used in the particular setting of DRC to control *Glossina fuscipes quanzensis* in an integrated program combining active and passive screening with vector control. Between 2015 and 2018, tsetse control has been scaled up from an area of 500km^2 to 2700km^2 across Yasa-Bonga and Masi-Manimba Health Zones. Between 3000 and 12000 Tiny Targets were deployed at six-month intervals in riverine areas where tsetse concentrate and the catch of tsetse from a network of 250 monitoring traps declined by over 90% within three months of targets being deployed. The operation was implemented by locally-recruited people who had no prior experience of tsetse control; after one day of training they deployed targets largely from dugout canoes navigating along major rivers. By 2018, planning, management and supervision of the operation was conducted by a single entomologist from the national control program ('Programme National de Lutte contre la Trypanosomiase Humaine Africaine', PNLTHA). Tiny Targets offer a simple and cost-effective method of tsetse control which can be readily implemented by local people with technical guidance from a national vector control program. Tsetse control operations are currently being expanded across Bandundu in what we expect will be the largest vector control operation against gHAT ever.

2074

PARATRANSGENIC MANIPULATION OF MICRORNA-275 EXPRESSION IN THE TSETSE FLY MIDGUT, AND THE DOWNSTREAM IMPACT ON TRYPANOSOME INFECTION OUTCOMES

Brian L. Weiss[1], Aurelien Vigneron[1], Adeline E. Williams[1], Liu Yang[1], Mehmet Karakus[1], Emre Aksoy[2], Serap Aksoy[1]

[1]Yale School of Public Health, New Haven, CT, United States, [2]University of California, Riverside, Riverside, CA, United States

Tsetse flies (*Glossina* spp.) are prominent vectors of pathogenic African trypanosomes. To establish an infection in tsetse, trypanosomes must cross the fly's peritrophic matrix (PM), which is a chitinous barrier that lines the midgut's luminal surface. Upon entering tsetse's midgut, bloodstream form parasites shed their variant surface glycoproteins (VSG), which are then internalized by the fly's PM-producing cardia organ. This process results in down-regulated expression of a tsetse microRNA (miR-275) that regulates the production of proteinaceous components

of the fly's PM. The molecular mechanisms that govern this pathway are poorly understood. To better define the impact of this microRNA on PM formation processes, we developed a novel *in vivo* 'paratransgenic' system that employs tsetse's commensal endosymbiont, *Sodalis*, to constitutively express a miR-275 antagomir (ant-275) or a scrambled control miR (scr-275) in the fly's gut. We stably colonized tsetse with either ant-275 or scr-275-expressing *Sodalis*, and confirmed miR-275 knockdown in the cardia of treatment flies compared to control flies. Subsequently, we used RNA-seq to determine the impact of miR-275 depletion on downstream gene expression in cardia tissue, and we monitored trypanosome infection outcomes in both lines of paratransgenic tsetse. We found that knockdown of miR-275 expression in tsetse's cardia sequentially altered the expression of genes that encode PM associated proteins. Furthermore, treatment flies were significantly more susceptible to infection with trypanosomes than were control individuals. Our results demonstrate the efficacy of using paratransgenesis to express and study the function of microRNAs in an animal host-commensal symbiont model system. Using the tsetse fly in this capacity, we characterize in detail the role of miR-275 in regulating trypanosome infection outcomes in the fly. This powerful tool can be further developed for use in unraveling the molecular mechanisms that underlie trypanosome-tsetse interactions.

2075

CHAGAS DISEASE ECO-EPIDEMIOLOGY: VECTOR HOST-FEEDING PATTERNS SUGGEST AN EPIDEMIOLOGICAL RISK OF CHAGAS DISEASE ON THE CARIBBEAN ISLAND OF TRINIDAD

Alexandra Eakes[1], Daniel Fitzpatrick[2], Andrew Dobson[1], Rod Suepaul[3], **Jennifer Kate Peterson**[1]

[1]Princeton University, Princeton, NJ, United States, [2]St. George's University, St. George's, Grenada, [3]University of the West Indies, Mount Hope, Trinidad and Tobago

Chagas disease, (etiological agent *Trypanosoma cruzi*), is not recognized as an epidemiological risk in the Caribbean, due in part to a belief that the triatomine bug vectors in the region do not feed on humans. Lending evidence to the contrary, three studies on the Caribbean island of Trinidad found *T. cruzi*-infected triatomine bugs and *T.* cruzi-seropositive humans with clinical features of Chagas disease. However, there have been no reports of direct contact between humans and triatomine bugs on the island, begging the question, are the bugs feeding on humans? To answer this question and gain a better understanding of the epidemiological risk of Chagas disease in Trinidad, we analyzed blood meals from triatomine bugs collected near human homes from five sites in northern and central Trinidad. For each bug, we diagnosed *T. cruzi* infection, and sequenced its DNA to determine the last host species from which it fed. Out of 55 bugs (54 *Panstrongylus geniculatus* and 1 *Rhodnius pictipes*), 46 (83.6%) were infected with *T. cruzi*. DNA sequencing yielded conclusive host identification for 48 (87.3%) of the 55 bugs. The most common hosts were humans (25 bugs; 52.1%), followed by chickens (10 bugs; 20.1%), sylvatic mammals (10 bugs; 20.1%), and sylvatic birds (3 bugs; 6.2%). Of the 25 bugs that fed on humans, 21 (84%) were infected with *T. cruzi.* At least one bug from each of the five collection sites was infected with *T. cruzi*, and at least one bug from each site had taken a human blood meal. *T. cruzi*-infected bugs with human blood meals were found at three of the sites. Ecologically, our findings suggest that in Trinidad, the triatomine bug species *P. geniculatus* feeds on a range of taxa across sylvatic and domestic habitats, a common characteristic of key Chagas disease vectors. Indeed, *P. geniculatus* is a competent vector of *T. cruzi,* and has been implicated in Chagas disease transmission in regions recognized as Chagas-endemic. Epidemiologically, our results suggest that humans are likely to be involved in a vector-borne *T. cruzi* transmission cycle in Trinidad, and that Chagas disease may be a higher epidemiological risk in Trinidad than previously believed.

2076

IMMUNE RESPONSE OF THE BED BUG TO SIMULATED TRAUMATIC INSEMINATION, STARVATION, AND INFECTION WITH ENTOMOPATHOGENIC BACTERIA

Jonas G. King, Aline Bronzato Badial, Travis van Warmerdam

Mississippi State University, MSU, MS, United States

The bed bug, *Cimex lectularius*, is a tenacious human pest. While bed bugs are thought to have evolved several immune-related adaptations to aid their remarkable lifestyle, the mechanisms involved in their innate immune response are poorly understood. Along with hematophagy, bed bugs are believed to undergo significant pathogen exposure during the process of traumatic insemination. During this process, male bugs pierce the female through her cuticle and inseminate the body cavity directly. As the bed bug genome is now available, we have the ability to measure gene regulation in response to immune challenge. Here, we used simulated traumatic insemination, or direct infection with a suite of entomopathogenic bacteria, followed by qRT-PCR-based analyses to measure the post-infection transcriptional response of conserved innate immunity-related genes. The primer sets used were designed and validated as part of this study and represent a novel immunity gene suite for this species. Current results suggest that antimicrobial peptides are generally upregulated in response to immune challenge in a pathogen and temperature dependent fashion, while several other immunity-related genes do not change significantly in response to infection or starvation. Current progress from an expanded suite of immune genes and pathogens will be presented along with a discussion of how this knowledge could be applied towards bed bug control.

2077

NOVEL VECTORS AND PARASITE OF CUTANEOUS LEISHMANIASIS TRANSMISSION IN GILGIL, NAKURU COUNTY, KENYA

Damaris K. Matoke-Muhia[1], Barrack O. Owino[2], Jackline M. Mwangi[3], Johnson Ingonga[3], Philip Ngumbi[3], Daniel K. Masiga[1]

[1]International Centre for Insect Physiology and Ecology, Nairobi, Kenya, [2]Livepool School of Tropical Medicine, Liverpool, United Kingdom, [3]Kenya Medical Research Institute, Nairobi, Kenya

Cutaneous leishmaniasis (CL), a Neglected Tropical Diseases is endemic in parts of Kenya. Phlebotomine sandflies are the only proven vectors of the disease but knowledge of their distribution and diversity in Kenya is scarce. Accurate knowledge of this is fundamental in implementation of vector control strategies. We explored occurrence, distribution and diversity of sandflies in Gilgil, Nakuru County, Kenya. Vector sampling was done from five villages, CL hot spots. Trapping was done using CDC light traps and castor oil sticky papers. Morphological and molecular identification of vector species was done using taxonomic keys and sequencing of the mitochondrial cytochrome c oxidase subunit 1 (COI) gene. Midguts of sandflies suspected to harbor promastigotes were cultured in NNN media overlaid with complete Schneider's media or blood agar. Parasite identification was done using PCR-high resolution melt of the ITS1 gene and sequencing. Cytochrome b (*cyt-b*) gene was analyzed for host preference determination. A total of 1320 sandflies were collected: Sergentomyia (8.5%) and phelebotomine (91.5%). For phlebotomine, 5 species were identified: *P. guggisbergi (*69%), *P. saevus* (18%), *P. sergenti* (2%), *P. aculeatus* (7%). Vectors were differentially distributed with 70% and 30% accounting for outdoor and indoor collection respectively. Both *Leishmania tropica* and *Leishmania major* parasites were isolated from *P. guggisbergi* while *L. tropica* was isolated from *P. saevus.* Blood-meal sources included: humans (75%), rock hyraxes (19%), rats (2%), rabbits (2%) and pigs (2%). This is the first report of natural infection of *P. saevus* with *L. tropica* and the first evidence of *P. guggisbergi* as a vector of both *L. tropica* and *L. major*, implying that these species are involved in transmission of CL in Kenya. The possibility of *P. guggisbergi*

as a permissive vector remains to be determined. This study also reports occurrence for the first time of *P. sergenti* in the study site. Indoor and outdoor vector control activities need to be implemented in the study area. Targeted sandfly control strategies should be implemented.

2078

HUMAN ANTIBODY RESPONSES AGAINST SALIVARY PROTEINS OF *AMBLYOMMA AMERICANUM*

Paulina Maldonado-Ruiz, Peter Klein, Ludek Zurek, Berlin Londono-Renteria

Kansas State University, Manhattan, KS, United States

Ticks are obligate blood-feeding ectoparasites and the most important arthropod vectors of human pathogens in the United States. The lone star tick, *Amblyomma americanum*, is widely distributed throughout the Midwest of the US, and it is a known vector of pathogens causing Rocky mountain spotted fever, tularemia, ehrlichiosis, STARI and a Lyme-like disease. There have been several studies about the immunologic response of the host when encountered with a tick-borne pathogen and host acquired immunity to ticks after tick feeding; however, little is known about other potential tick antigens that may affect the human host; whether it is bite associated or simply by contact. Nevertheless, it is important to elucidate which tick proteins and what mechanisms might be associated with a host immune response after exposure to ticks. Previous studies have shown the usefulness of antibodies against vector saliva as reliable markers for the human-vector contact and the disease transmission risk. In this study, we measured IgG, IgM and IgE antibodies against whole salivary gland extract of *A. americanum* in blood from individuals living in Kansas. We found a significant negative correlation between IgG and IgE antibody levels and age. Our analysis also shows that people using repellents have lower IgG antibodies against tick salivary proteins. We also found significantly lower antibodies in samples collected in the Fall respective to those collected during the Summer months. In addition, a western-blot test revealed three main immunogenic proteins identified by IgG antibodies (75, 45 and 37 kDa). Recombinant proteins will be used as biomarkers for human-tick exposure in an ELISA-based assay. Additionally, antibodies against pathogens can be correlated to the level of exposure to tick bites to calculate risk of disease. These results are the first report of immune responses to the lone start tick feeding in relationship to exposure in healthy individuals living in the US.

2079

EXPLORING THE SALIVARY GLYCOPROTEOME OF BLOODFEEDING ARTHROPODS AND THEIR RELEVANCE IN PATHOGEN TRANSMISSION

Karina Mondragon-Shem[1], Katherine Wongtrakul-Kish[2], Rad Kozak[2], Ricardo Araujo[3], Alexandre Marques[3], Daniel Spencer[2], Shi Yan[4], Iain Wilson[4], Katharina Paschinger[4], Matthew E. Rogers[5], Marcos Horacio Pereira[3], Alvaro Acosta-Serrano[1]

[1]Liverpool School of Tropical Medicine, Liverpool, United Kingdom, [2]Ludger, Oxford, United Kingdom, [3]Laboratório de Fisiologia de Insetos Hematófagos, Universidade Federal de Minas Gerais, Minas Gerais, Brazil, [4]University of Natural Resources and Life Sciences, Vienna, Austria, [5]London School of Hygiene & Tropical Medicine, London, United Kingdom

The saliva of hematophagous arthropods is a powerful cocktail of substances meant to facilitate bloodfeeding, by counteracting the host's healing processes. Saliva can also stimulate significant immune responses, but while most research has focused on the proteins it contains, the glycans (sugars) that modify them remain overlooked. As glycans can determine a protein's biological role, they can be responsible for the saliva's effects on pathogens and their transmission. Therefore, in this work we set out to characterise the salivary glycans of ticks (*Amblyomma cajennense*), mosquitoes (*Anopheles gambiae, Aedes aegypti*), tsetse flies (*Glossina morsitans*), sandflies (*Lutzomyia longipalpis*) and triatomines (*Rhodnius prolixus*). To do this, we dissected and harvested saliva from each of these arthropods and characterized the sugar structures using a glycomics approach. This included enzymatic treatment, followed by analyses through high-performance liquid chromatography in combination with highly sensitive mass spectrometry. Our work shows that the salivary glycoproteins of these vectors are mostly composed of *N*-linked mannose-type sugars; the comparison between species shows variations mainly in the abundance of these structures. Interestingly, there were hybrid sugars specific to each organism, with mosquitoes and tick glycoproteins in particular displaying the most striking and potentially immunogenic structures. As some receptors on host immune cells are specific for mannose structures, we also performed overlay assays using recombinant fractions of human mannose receptors; salivary glycoproteins from all species were positively recognised, hinting at *in vivo* interactions with macrophages and dendritic cells. These interactions may be responsible for the saliva-specific immune responses that affect the process of pathogen infection; additionally, they can have a role in the host clearance (half-life) of the salivary glycoproteins themselves. Finally, the similarities of the sugars found indicate suggests the presence of conserved pathways of salivary protein glycosylation.

2080

CRYOPRESERVATION OF INFECTIOUS *CRYPTOSPORIDIUM PARVUMOO* CYSTS

Justyna J. Jaskiewicz[1], Rebecca Sandlin[2], Giovanni Widmer[1], Anisa Swei[2], Mehmet Toner[2], Saul Tzipori[1]

[1]Cummings School of Veterinary Medicine at Tufts University, North Grafton, MA, United States, [2]Center for Engineering in Medicine, Massachusetts General Hospital, Charlestown, MA, United States

Cryptosporidiosis in an enteric infection caused by *Cryptosporidium* species and is a major cause of acute infant diarrhea in the developing world. The lack of methods to cryopreserve *Cryptosporidium* oocysts greatly hinders research on these parasites. Here, we report that ultra-fast cooling enables cryogenic storage of *C. parvum* oocysts. Cryopreserved oocysts exhibited high viability and robust *in vitro* excystation. Cryopreserved oocysts were infectious to interferon-γ knockout mice. The course of the infection was comparable to what we observed with unfrozen oocysts. Oocysts viability and infectivity was not visibly changed after several weeks of cryogenic storage. Cryopreservation will facilitate the sharing of oocysts from well characterized isolates among different laboratories.

2081

CHARACTERIZATION OF GENETIC VARIATION BETWEEN HOST-SPECIFIC *THEILERIA PARVA* POPULATIONS

Nicholas C. Palmateer[1], Claudia A. Daubenberger[2], Richard P. Bishop[3], Joana C. Silva[1]

[1]Institute for Genome Sciences, University of Maryland School of Medicine, Baltimore, MD, United States, [2]Swiss Tropical and Public Health Institute and University of Basel, Basel, Switzerland, [3]Department of Veterinary Microbiology and Pathology, Washington State University, Pullman, WA, United States

East Coast Fever (ECF), caused by the apicomplexan parasite *Theileria parva*, kills more than a million cattle each year, in the regions of sub-Saharan Africa where the disease is endemic. The African Cape buffalo is believed to be the natural reservoir of *T. parva* and rarely exhibits clinical symptoms when infected, but transmits the parasite to cattle via a tick vector. A vaccine for ECF exists, which is effective against cattle-transmissible strains but much less effective in protecting cattle from *T. parva* strains originating in buffalo. Previous studies based on a few genetic markers have shown that buffalo-derived *T. parva* populations contain greater antigenic diversity, possibly explaining the failure of the vaccine to protect against the more diverse buffalo-derived parasites. Interestingly, cattle is infected and killed by *T. parva* of buffalo origin, but cannot transmit those parasites, suggesting that a degree of host specificity has occurred. The characterization of genetic variation among

and between cattle- and buffalo-derived *T. parva* strains is critical to shed light on the evolutionary processes that have led to the host specificity, as well as for the design of next-generation vaccines against all strains. We generated whole genome sequence data from 25 cattle- and 28 buffalo-derived *T. parva* isolates following whole genome DNA sequence capture. Based on genome-wide SNP data, we identified genomic islands of divergence between the cattle- and buffalo-derived *T. parva* isolates. An F_{ST} analysis yielded a genome-wide value of 0.27 between the two sets of strains, revealing strong differentiation. Known antigens Tp8, Tp10, and p67 were among the genes with highest F_{ST} values, warranting further exploration for vaccine development. We are mining regions with strongest differentiation for genes with a potential role in infection and transmission, based on the function and properties of the encoded proteins.

2082

NOVEL ASSAYS FOR ANTICRYPTOSPORIDIAL *IN VITRO* EFFICACY

Alexander T. Chao

Novartis Institutes for Biomedical Research, Emeryville, CA, United States

Novel assays for anticryptosporidial *in vitro* efficacy Cryptosporidiosis is a diarrheal disease predominantly caused by *Cryptosporidium parvum* (*Cp*) and *Cryptosporidium hominis* (*Ch*), apicomplexan parasites which infect the intestinal epithelial cells of their human hosts. The only approved drug for cryptosporidiosis is nitazoxanide, which shows limited efficacy in immunocompromised children, the most vulnerable patient population. New therapeutics and *in vitro* infection models are urgently needed to address the current unmet medical need. Toward this aim, we have developed novel cytopathic effect (CPE)-based *Cp* and *Ch* assays in human colonic tumor (HCT-8) cells and compared them to traditional imaging formats. Further model validation was achieved through screening a collection of FDA-approved drugs and confirming many previously known anti-*Cryptosporidium* hits as well as identifying a few novel candidates. Collectively, our data reveals this model to be a simple, functional, and homogeneous gain of signal format amenable to high throughput screening, opening new avenues for the discovery of novel anticryptosporidials.

2083

EUKARYOTYPING: A NOVEL METHOD FOR AIDING OUTBREAK INVESTIGATIONS INVOLVING THE SEXUAL EUKARYOTIC PATHOGEN *CYCLOSPORA CAYETANENSIS*

Joel Barratt, Subin Park, Fernanda Nascimento, Jessica Hofstetter, Shannon Casillas, Mateusz Plucinski, Richard Bradbury, Michael Arrowood, Yvonne Qvarnstrom, Eldin Talundzic

Centers for Disease Control and Prevention, Atlanta, GA, United States

Cyclospora cayetanensis is an intestinal protozoan of humans responsible for seasonal outbreaks of foodborne illness in the United States (U.S.) due to importation of contaminated fresh produce from endemic countries. No independently validated molecular tools have been developed to aid cyclosporiasis outbreak investigations. *Cyclospora* reproduces sexually and possesses three discrete genomes, one nuclear and two organellar, resulting in a complex genetic structure and intra-isolate heterozygosity which complicates typing using traditional multi-locus-sequencing approaches. Additionally, the availability of only two published *C. cayetanensis* genomes hinders selection of informative typing markers. We sequenced 11 *C. cayetanensis* genomes and identified three Polymerase Chain Reaction (PCR) enrichment friendly markers, including two nuclear loci and one mitochondrial locus. We applied PCR enrichment and Sanger sequencing of these loci to 74 fecal specimens containing *C. cayetanensis*, 27 of which had been epidemiologically linked to U.S. cyclosporiasis outbreaks. Next, we developed a novel method, eukaryotyping, which incorporates machine learning approaches to identify genetic clusters that represent parasite familial relationships, and used it to analyze the sequence data. Eukaryotyping differs from other methods as it considers intra-isolate heterozygosity, a common feature of nuclear loci in sexual eukaryotes partly attributable to their mechanisms of nuclear inheritance. This is an important advancement, as heterozygosity confounds traditional approaches, sometimes resulting in exclusion of data. Eukaryotyping resolved the parasites within the 74 fecal specimens into 10 genetic clusters, represented as a 2D scatter-plot for ease of interpretation. These clusters were largely corroborated by the epidemiological data, supporting the utility of eukaryotyping for assisting epidemiological trace-back. While the markers examined here are specific to *C. cayetanensis*, the principals behind eukaryotyping will likely have broader implications that extend to other sexual eukaryotic pathogens.

2084

EVALUATION OF THREE COMMERCIAL DIAGNOSTIC TESTS FOR *CRYPTOSPORIDIUM* INFECTIONS IN HUMANS

Henk Schallig[1], Joseph Bitilinyu-Bangoh[2], Wieger Voskuijl[1]

[1]Academic Medical Centre, Amsterdam, Netherlands, [2]Queen Elizabeth Central Hospital, Blantyre, Malawi

Diarrhea is the second greatest killer of small children worldwide, responsible for 800.000 deaths of under 4-year-olds yearly. Most lethal diarrhea in small children is caused by rotavirus, which is soon to be controlled by vaccination programs. This is closely followed by the eukaryote *Cryptosporidium,* which is one of the commonest, and at the same time most poorly understood, water-borne parasites of humans. To aid diagnosis and to support control programmes adequate diagnostic tests should be in place. Several rapid diagnostic tests (RDTs) for cryptosporidiosis are nowadays available and we have evaluated three different brands: RIDA QUICK for *Cryptosporidium/Giardia* Combi (R-Biopharm, Germany); CRYPTO/GIARDIA DUO-Strip (Coris BioConcept, Belgium); GIARDIA/CRYPTOSPORIDIUM QUIK CHEK (TechLab, USA). All three test are based on the lateral flow principle, able to detect both *Cryptosporidium* as well as *Giardia* and are sold as complete test kits. Stool samples of children from Malawi or Kenya suspected of having a protozoan infection causing diarrhea were used for diagnostic evaluation using PCR as reference standard. The Cryptosporidium incidence based on antigen detection was calculated to range from 9.5% to 18.1% in the samples from Malawi and from 15.0% to 25.0% in the Kenyan samples. The majority of stool samples from Malawi (71.4%), as well as Kenya (84%), was typed as "C. hominis". Infections with only "C. parvum" were less abundant (22.9% and 11.5% for Malawi and Kenya, respectively) and there were no mixed Cryptosporidium species infections. The Giardia incidence on the basis of RDTs ranged from 12.1% to 19.8% and from 6.7% to 12.5% in the Malawian and Kenyan samples, respectively. Using PCR as reference standard the sensitivity and specificity of the tests was respectively as follows: DUO 59.4% (95% CI: 47.9 - 70.4) and 95.5% (95% CI: 91.0 - 98.1%); RIDA: 67.1% (95% CI: 55.6 - 77.3%) and 83.4% (95% CI: 76.7 - 88.9%) and QUICK 76.0% (95% CI: 65.0 - 84.9%) and 96.2% (95% CI: 91.9 - 98.6%). The QUICK test had the best agreement with PCR (k-value: 0.760, SE of Kappa: 0.043, 95%CI: 0.676 - 0.845; agreement is considered: "good").

2085

POTENT AND SELECTIVE ANTI-*GIARDIA* COMPOUND SERIES: PROGRESS AND NEW DEVELOPMENTS

Tina S. Skinner-Adams[1], Chris J. Hart[1], Andrew Riches[2], Jack Ryan[2], Sam Abraham[3], Rebecca Abraham[3]

[1]Griffith University, Brisbane, Australia, [2]Commonwealth Scientific and Industrial Research Organization, Melbourne, Australia, [3]Murdoch University, Perth, Australia

Giardia duodenalis infects a wide array of hosts and is the most frequently reported human intestinal parasite. On an annual basis this parasite is responsible for ~1 billion human infections of which >200 million result in symptomatic disease. While infections are more prevalent in the

developing world, this parasite is ubiquitous. *Giardia* infection can result in severe and chronic disease, causing malabsorption, weight loss and failure to thrive in children. There is also evidence that infection is linked to post-infection disorders including irritable bowel syndrome. Despite growing evidence of *Giardia* associated morbidity, current treatment options are inadequate. The frontline drug, metronidazole (MTZ), is associated with side-effects and drug resistance. It is also incredibly distasteful and must be taken in multiple doses over 5-7 days, factors which result in poor compliance, treatment failure, rapid re-infection and parasite resistance. In addition there is increasing evidence that MTZ has a collateral effect on host microbiome. To improve giardiasis treatment options in the long-term we recently screened compounds from the Compounds Australia Open Access Scaffold Library for anti-*Giardia* activity (2451 compound subset; 2/scaffold; Z-factor 0.75). Rational selection based on activity, novelty, and chemical liabilities identified three compound series with potent (IC_{50}≤1μM) and selective activity for *G. duodenalis.* These compound series have been chosen as starting points for anti-*Giardia* drug development. The most promising compound identified to date is active against assemblage A, B and metronidazole resistant parasites (290-fold more potent than metronidazole) and has a *Giardia* vs human selectivity index of >9000. Preliminary *in vivo* studies with this compound suggest no toxicity at up to 10X the calculated therapeutic dose and ~75% efficacy at a dose of 0.7mg/kg daily for 3 days. Further *in vivo* and activity studies with this compound and other lead series candidates are now under way and will be presented.

THE EFFECTS OF NITIDINE CHLORIDE AND CAMPTOTHECIN ON THE GROWTH OF *BABESIA* AND *THEILERIA* PARASITES

Ikuo Igarashi, Dickson S. Tayebwa, Bumduuren Tuvshintulga, Azirwan Guswanto, Thillaiampalam Sivakumar, Naoaki Yokoyama

National Research Center for Protozoan Diseases, Obihiro University of Agriculture and Veterinary Medicine, Obihiro, Japan

The treatment of bovine and equine piroplasmosis is limited to diminazene aceturate (DA) and imidocarb dipropionate. To address this challenge, we need to explore novel drug compounds and targets. Topoisomerases are potential drug targets because they play a vital role in solving topological errors of DNA strands during replication. This study documented the effectiveness of topoisomerase inhibitors, nitidine chloride (NC) and camptothecin (Cpt), on the growth of *Babesia* and *Theileria* parasites. The half maximal inhibitory concentrations (IC_{50}s) against *B. bovis*, *B. bigemina*, *B. caballi*, and *T. equi* were 1.01 ± 0.2, 5.34 ± 1.0, 0.11 ± 0.03, and 2.05 ± 0.4 μM for NC and 11.67 ± 1.6, 4.00 ± 1.0, 2.07 ± 0.6, and 0.33 ± 0.02 μM for Cpt, respectively. The viability experiment showed that *B. bovis*, *B. bigemina*, and *B. caballi* did not regrow in 4, 10, and 4 μM or 48, 8, and 8 μM treatments of NC and Cpt, respectively. However, *T. equi* regrew in all of the concentrations used. Moreover, increasing the concentration of NC and Cpt to 16 μM and 1.2 μM (8×IC_{50}) did not eliminate *T. equi*. The micrographs of *B. bigemina* and *B. caballi* taken at 24 h and 72 h showed deformed merozoites and remnants of parasites within the RBC, respectively. The treatments of 25 mg/kg DA and 20 mg/kg NC administered intraperitoneally and 20 mg/kg NC given orally showed 93.7, 90.7, and 83.6% inhibition against *B. microti*, respectively, compared to the untreated group on day 8. In summary, NC and Cpt were effective against *Babesia* and *Theileria* parasites *in vitro*. Moreover, 20 mg/kg NC administered intraperitoneally was as effective as 25 mg/kg DA against *B. microti* in mice and showed no toxic symptoms in mice. The results indicate that NC may, after further evaluations, prove to be an alternative drug against bovine and equine piroplasmoses.

A TRIAL OF A NOVEL TRIPLE DRUG TREATMENT FOR LYMPHATIC FILARIASIS IN PAPUA NEW GUINEA

Christopher L. King[1], James Suamani[2], Nelly Sanuku[2], Yao-Chieh Cheng[1], Samson Satofan[2], Brooke Mancuso[1], Leanne Robinson[3], Peter Siba[2], Gary Weil[4], James W. Kazura[1]

[1]Case Western Reserve University, Cleveland, OH, United States, [2]Papua New Guinea Institute of Medical Research, Papua New Guinea, Goroka, Papua New Guinea, [3]Burnett Institute, Melbourne, Australia, [4]Washington University, St Louis, MO, United States

A single dose of diethylcarbamazine (DEC) plus albendazole (ALB) given for multiple annual treatments are required for elimination of lymphatic filariasis outside sub-Saharan Africa since a single dose does not reduce blood microfilaria counts below the threshold required to interrupt transmission. This study tested the efficacy of single dose of ivermectin (IVM) combined with DEC/ALB and provides the final results of this clinical trial. We conducted a randomized clinical trial in which *Wuchereria bancrofti*-microfilaremic adults in Papua New Guinea were assigned to treatment with IVM/DEC/ALB once (n=60), DEC/ALB once (n=61), and DEC/ALB annually for 3 years (n=61). Clearance of blood microfilaria was measured at 12, 24 and 36 months. A single dose of IVM/DEC/ALB cleared microfilaremia in 55 of 57 (96%), 52 of 54 (96%) and 55 of 57 study participants (96%) at 12, 24 and 36 months, respectively. At the same time points one dose of DEC/ALB cleared microfilaremia in 18 of 56 participants (34%), 31 of 55 (56%), and 43 of 52 (83%) (relative risk to IVM/DEC/ALB at 36 months=0.20 P=0.035). 20 of 59 (32%), 42 of 56 (75%) and 51 of 52 participants (98%) treated with DEC/ALB annually for 3 years cleared microfilaremia over the same time period. Moderate adverse events were more common after treatment with the triple- than two-drug regimen (27% vs. 5%, P<0.001). There were no serious adverse events. A single dose of IVM/DEC/ALB induced rapid and sustained clearance of blood microfilaria in almost all individuals for 3 years and was superior to one dose or three annual doses of DEC/ALB.

2088

OXFENDAZOLE TREATMENT HAS A MACROFILARICIDAL EFFICACY AGAINST THE FILARIAL NEMATODE *LITOMOSOIDES SIGMODONTIS IN VIVO* AND INHIBITS *ONCHOCERCA GUTTUROSA* ADULT WORM MOTILITY *IN VITRO*

Marc P. Hübner[1], Coralie Martin[2], Sabine Specht[1], Marianne Koschel[1], Bettina Dubben[1], Stefan J. Frohberger[1], Alexandra Ehrens[1], Martina Fendler[1], Dominique Struever[1], Nathaly Vallarino-Lhermitte[2], Suzanne Gokool[3], Simon Townson[3], Achim Hoerauf[1], Ivan Scandale[4]

[1]Institute for Medical Microbiology, Immunology and Parasitology, University Hospital Bonn, Bonn, Germany, [2]Unité Molécules de Communication et Adaptation des Microorganismes (MCAM, UMR 7245), Sorbonne Universités, Muséum national d'Histoire naturelle, CNRS, Paris, France, [3]Tropical Parasitic Diseases Unit, Northwick Park Institute for Medical Research, Harrow, Middlesex, United Kingdom, [4]Drugs for Neglected Diseases initiative, Geneva, Switzerland

Oxfendazole (OXF) is a promising drug candidate for the elimination of onchocerciasis that is closely related to the macrofilaricidal benzimidazole flubendazole (FBZ), but possesses an improved oral bioavailability. In the current study, we evaluated the *in vitro* efficacy of OXF against *Onchocerca gutturosa* adult filariae and *Onchocerca lienalis* microfilariae and compared the *in vivo* efficacy of OXF and FBZ in the *Litomosoides sigmodontis* rodent model of filariasis. OXF inhibited the motility of *O. gutturosa* adult worms in a dose dependent manner and had only marginal effects against *O. lienalis* microfilariae. Accordingly, OXF lacked a microfilaricidal efficacy in mice injected with *L. sigmodontis* microfilariae, whereas 5 days of subcutaneous administrations with OXF (25mg/kg) and FBZ (2, 6, 20mg/

kg) completely cleared the adult worm burden in *L. sigmodontis* infected mice. A complete clearance of the *L. sigmodontis* adult worm burden was also achieved by 5 days of oral treatments with OXF (2x12.5, 2x25mg/kg), but not FBZ (2, 6mg/kg). Oral OXF treatments (10 days, 2x5mg/kg) of patently *L. sigmodontis* infected jirds reduced the peripheral microfilaremia by >99% within 3 weeks post treatment start and a complete inhibition of the embryogenesis of remaining female adult worms was determined at necropsy, 16 weeks after treatment start. Pharmacokinetic analysis of OXF identified exposure time over threshold as driver of efficacy. These results indicate that OXF has an excellent macrofilaricidal efficacy following oral and subcutaneous administrations, but lacks a strong microfilarcidal efficacy, which reduces the risk of associated severe adverse events. Ongoing evaluations in a phase II study for trichuriasis and a multiple ascending dose phase I study will further help to consider the potential of OXF as clinical candidate for human filarial infections.

CLINICAL PRESENTATIONS OF ONCHOCERCIASIS-ASSOCIATED EPILEPSY IN CAMEROON

Joseph Nelson Siewe Fodjo[1], Ernest Nji Tabah[2], Leonard Ngarka[3], Leonard Nfor Njamnshi[4], Samuel Eric Chokote[3], Michel Mengnjo K[3], Fidele Dema[5], Grace Nkoro[6], Anne Cecile Zoung-Kanyi Bissek[2], Alfred Njamnshi K[3], Robert Colebunders[1]

[1]Global Health Institute, University of Antwerp, Antwerp, Belgium, [2]Ministry of Public Health, Yaounde, Cameroon, [3]Neurology Department, Yaounde Central Hospital, Yaounde, Cameroon, [4]Neurology Department, Centre Hospitalier Universitaire Brugman, Brussels, Belgium, [5]Yoko District Hospital, Yoko, Cameroon, [6]Neuroscience Laboratory, Faculty of Medicine and Biomedical Sciences, University of Yaounde I, Yaounde, Cameroon

Onchocerciasis (oncho) is known to cause skin and eye disease. However, reports from oncho-meso and hyper-endemic areas reveal a high prevalence of epilepsy with a wide spectrum of seizure disorders constituting onchocerciasis-associated epilepsy (OAE). Data on the clinical features of OAE is currently scarce, whereas it is most likely the first cause of mortality due to oncho. Door-to-door surveys were carried out between July 2017 and January 2018 in 5 oncho-endemic villages in Cameroon. Epilepsy diagnosis was done in 2 steps: administration of a standard 5-items questionnaire and confirmation of suspected cases by a neurologist. OAE was defined as ≥2 seizures without an obvious cause, starting between the ages of 5-18 years in previously healthy persons having resided for at least 3 years in an oncho area. PWE were examined and relevant history including birth conditions, health during childhood, seizure types and ivermectin (IVM) use were noted. Rapid tests were done to qualitatively assess the presence of anti-Ov16 antibodies. 156 PWE were recruited; the frequent seizure types were generalized tonic-clonic seizures (89%) and absences (39%). 34 PWE (22%) with nodding seizures (NS) and 1 case with Nakalanga features were identified. Mixed seizure types were seen in 40%; moreover in certain PWE, the seizure spectrum varied over time. 93% of all PWE met the diagnostic criteria for OAE. 57% of PWE tested positive for Ov16, but no clinical difference was observed with those who were Ov16-negative. In one village, 56% of PWE had onchocercal skin lesions confirmed by a dermatologist. Only 28% of PWE had taken ivermectin prior to the onset of seizures. In oncho-endemic areas in Cameroon, OAE presents as a spectrum of seizure types including NS. Onchocercal skin lesions and anti-Ov16 antibodies may be associated. Such clinical pictures should evoke a potential link with oncho. Although OAE pathophysiology is still unclear, its onset may be favored by poor IVM prophylaxis.

2090

A TRIAL OF SINGLE DOSE IVERMECTIN, DIETHYLCARBAMAZINE AND ALBENDAZOLE FOR TREATMENT OF LYMPHATIC FILARIASIS IN SUB-SAHARAN AFRICA

Catherine M. Bjerum[1], Allassane Ouattara[2], Aboulaye Meite[3], Benjamin Koudou[4], Koffi Marius Vanga[2], Olivier Kouadio[2], Gary Weil[5], Christopher King[1]

[1]Case Western Reserve University, Cleveland, OH, United States, [2]Centre Suisse de Recherche Scientifique en Côte d'Ivoire, Abidjan, Côte D'Ivoire, [3]Programme national de la lutte contre l'onchocercose, la schistosomiase, les geohelminthiases et la filariose lymphatique, Abidjan, Côte D'Ivoire, [4]Liverpool School of Tropical Medicine, Liverpool, United Kingdom, [5]Infectious Diseases Division, Department of Internal Medicine, Washington University School of Medicine, St. Loius, MO, United States

The recommended drug regimen for elimination of lymphatic filariasis in sub-Saharan Africa is a single dose of ivermectin (IVM) plus albendazole (ALB). Multiple annual treatments are required for elimination since a single dose of this regimen does not reduce blood microfilaria counts below the threshold required to interrupt transmission. Recent studies in Papua New Guinea have shown that a single dose of co-administered IVM, diethylcarbamazine (DEC) and ALB can sustain complete clearance of microfilariae (Mf) in 96% of participants for 3 years. This study examined the efficacy of a single dose of IVM+DEC+ALB in sub-Saharan Africa. We conducted an open-labeled, single-blinded clinical trial in which *Wuchereria bancrofti*-microfilaremic adults from Cote d'Ivoire were randomized to treatment with either a single dose of IVM+DEC+ALB (IDA, N=42) or IVM+ALB annually for 3 years (IA, N=45). Clearance of blood microfilaria and inactivation of adult worm nests were measured at 6, 12, 24 and 36 months. 36 month data will be collected in July 2018. One dose of IDA completely cleared Mf in 34/35 (97%), 29/38 (76%) and 23/36 (64%) of individuals at 6, 12, and 24 months respectively. In contrast, IA given annually x 2 achieved clearance in 17/45 (38%), 11/45 (24%) and 22/40 (55%) at the same time points (risk relative [RR] to IDA=0.12, P=0.037 at 6 months, RR=0.31, P=0.0001 at 12 months, and RR=0.80, P=0.44 at 24 months). IDA also demonstrated greater inactivation of adult worm nests in participants with worm nests; 10/15 (67%) and 16/19 (84%) and 14/20 (70%) at 6, 12 and 24 months. By comparison IA inactivated worm nests in 6/22 (27%), 7/25 (28%) and 14/28 (50% risk relative to IDA=0.6, P=0.19 at 24 months) at the same time points. New worm nests were observed in 10, 3 and 1 men treated with IA at 6, 12 and 24 months respectively, compared with no men at 6 or 12 months and 2 men at 24 months treated with IDA (P=0.001, P=0.083, P=0.397 at 6, 12 and 24 months respectively). Treatment with a single dose of IDA is superior to IA at 12 months and non-inferior to two doses of IA at 24 months. Re-infection may contribute to the lack of sustained Mf clearance at 24 months.

CORALLOPYRONIN A: AN EFFECTIVE ANTIWOLBACHIAL COMPOUND FOR THE TREATMENT OF FILARIAL INFECTIONS AND ANTIBIOTIC FOR ANTIMICROBIAL RESISTANT STIS

Kenneth Pfarr[1], Andrea Schiefer[1], Anna Krome[2], Stefan Kerhaus[2], Stephan Hüttel[3], Rolf Jansen[3], Domen Pogorevc[4], Sarah Bouhired[2], Martin Roth[5], Gabriele M. König[2], Rolf Müller[4], Karl Wagner[2], Marc Stadler[3], Achim Hoerauf[1]

[1]University Hospital Bonn, Bonn, Germany, [2]University of Bonn, Bonn, Germany, [3]Helmholtz Centre for Infection Research, Braunschweig, Germany, [4]Helmholtz Centre for Infection Research, Saarland, Germany, [5]Hans-Knöll-Institute, Jena, Germany

Depleting essential *Wolbachia* endosymbionts from filarial nematodes (*Wuchereria bancrofti*, *Brugia* spp. and *Onchocerca volvulus*, causing lymphatic filariasis and onchocerciasis) with antibiotics blocks

development and kills adult worms more effectively than ivermectin or diethylcarbamazine, which are mainly microfilaricidal. Antiwolbachial therapy is a novel way to eliminate these poverty related diseases affecting >100 Mio people. Alternatives to doxycycline and rifampicin are required. Corallopyronin A (CorA) inhibits bacterial DNA dependent RNA polymerase. CorA MoA is different to rifamycins and is active against rifampicin-resistant *S. aureus*. Although not effective against most Gram-negative bacteria, CorA depletes *Wolbachia* >10-fold better than the gold standard doxycycline, resulting in >90% macrofilaricidal activity in jirds. Within the German Center for Infection Research (DZIF) we are developing CorA to treat filarial infections, and for the Global Antibiotic Research & Development Partnership (GARDP) priority program for gonorrhea. We conducted non-GLP ADME and *in vitro* toxicity studies showing that CorA: has similar PO and IP bioavailability, and is non-toxic and does not inhibit host cell proliferation. The expression of CYP450s is not altered and CP450 3A4 is minimally induced, limiting drug-drug interactions seen with rifampicin. It is stable in human, mouse and dog microsomes and is metabolized via phase I reactions. With heterologous expression of the biosynthetic genes in *Myxococcus xanthus*, we achieved gram-scale, cost-effective production of CorA. We also developed an efficient downstream process, guided by quantitative NMR and LC/MS, to yield >95% pure CorA. Using this CorA in the *Litomosoides sigmodontis* rodent infection model, we reduced the minimal effective *in vivo* dose 6-fold and treatment time to 7-10 days, fitting the macrofilaricidal TPP. The final production protocol will provide pure CorA for final non-GLP activities, including dose escalation tox, Ames and hERG tests. Partnering with a CMO to produce GMP CorA, we will conduct GLP-tox studies and plan a phase 1 trial with BfArM.

DEVELOPMENT AND VALIDATION OF AN *ONCHOCERCA OCHENGI* ADULT MALE WORM IN GERBIL MODEL FOR MACROFILARICIDAL DRUG DEVELOPMENT

Fidelis Cho-Ngwa[1], Glory E. Mbah[1], Rene B. Ayiseh[1], Emmanuel M. Ndi[1], Elvis Monya[1], Irene M. Tumanjong[1], Evans N. Mainsah[1], Judy Sakanari[2], Sara Lustigman[3]

[1]University of Buea, Buea, Cameroon, [2]University of California, San Francisco, CA, United States, [3]New York Blood Center, New York, NY, United States

Onchocerciasis currently afflicts an estimated 18 million people and is the second leading infectious cause of blindness world-wide. The development of a macrofilaricide to cure the disease has been hindered by the lack of appropriate small laboratory animal models. To overcome this challenge, we developed and validated a Mongolian gerbil model that supports the implantation of the closely related *Onchocerca ochengi* male worms from cattle in the peritoneum of the small animal. Animals were treated with drug or the vehicle three days after worm implantation. The implanted worms were recovered and analyzed for viability 35 days after. In control animals, the recovery of the worms was on average 36%, with 90% of them being 100% motile. During model validation, only 6% of the worms were recovered in animals treated with Flubendazole (FBZ), resulting in significant reduction of worm burden. Notably, the motility of the recovered male worms was 0% in FBZ group versus 91.1% in controls. FBZ was further tested in five different experiments of the model and the results were all similar. We used the validated model to test a related drug, Oxfendazole (OFZ) and found that it also significantly reduced worm burden by 52.7%. The motility of recovered worms in the OFZ group was 22.7% versus 95.0% in the controls. In conclusion, we have developed and validated a gerbil *O. ochengi* adult male worm model for testing new macrofilaricidal drugs *in vivo*, and have used it to show that Oxfendazole is a potential macrofilaricidal candidate. *Supported by grants from the Bill & Melinda Gates Foundation (OPP1098475 and OPP1017584)*

PROGRESS IN THE DEVELOPMENT OF NEEM EXTRACT AS A NOVEL ANTHELMINTIC THERAPEUTIC

Belinda M. Jackson-Thompson, So Young Kim, Jatinder Singh, Edward Mitre

Uniformed Services University, Bethesda, MD, United States

Despite the large burden of disease caused by helminths, there are currently very few medications available to treat these parasitic infections. We demonstrate that extract from the Neem tree (*Azadirachta indica*), used in Indian Ayurvedic medicine, has *in vitro* activity against tissue-invasive filariae that cause diseases such as elephantiasis and river blindness. Additionally, we have preliminary *in vivo* evidence that shows Neem efficacy in reducing adult worm burdens in *L. sigmodontis* infected mice. Neem extract was produced by partitioning the aqueous phase of the tree's seed oil, and then precipitating the small molecules. The precipitate was dissolved in a working stock of 2.5% ethanol. *In vitro*, we placed single adult *Brugia malayi* or *Litomosoides sigmodontis* worms, or pairs of *Schistosoma mansoni* worms, in 1 ml of media containing Neem extract at various concentrations. Worms were monitored daily for motility, fecundity, and viability. The extract rapidly kills adult *B. malayi* and *L. sigmodontis worms* within 5 days at 25 mcg/ml and within 1 day at 100 mcg/ml. *Schistosoma mansoni* worms were killed within 2 days of exposure at 100 mcg/ml. *In vivo,* BALB/c mice were infected subcutaneously with 40 L3 stage *L. sigmodontis* worms and treated seven weeks post-infection with 25 or 50 mg/kg of Neem extract by intraperitoneal injection. Two weeks following treatment, animals were euthanized and adult worms enumerated. A single dose of Neem extract at 50 mg/kg decreased the adult worm burden in these mice by over 50%. Fractionation analysis is currently under way to identify the specific active molecules within the Neem extract that exert anthelmintic activity. Additionally, we are analyzing several commercially available components of Neem and have had some success in demonstrating possible repurposing efficacy. This study demonstrates that Neem extract has broad-based anthelmintic activity against the two filarial pathogens tested and against *Schistosoma mansoni*. Neem exhibits excellent potential as a novel anthelmintic agent.

MODERNIZING OUTBREAK INVESTIGATION FOR EMERGING INFECTIONS: AN INTEGRATED PHYLOGENETIC AND EPIDEMIOLOGICAL APPROACH FROM THE WEST AFRICAN EBOLA OUTBREAK IN SIERRA LEONE DETECTS A POTENTIAL NOVEL MECHANISM OF TRANSMISSION AND VALIDATES THE BENEFIT OF INCORPORATING GENOMIC DATA

Cordelia Coltart[1], Daniel Cooper[2], Maria Calvo Cortes[3], Matthew Cotton[4], Ian Goodfellow[5], Anne Johnson[1], Stephane Hue[3]

[1]University College London, London, United Kingdom, [2]Menzies School of Health Research and Charles Darwin University, Darwin, Australia, [3]London School of Hygiene & Tropical Medicine, London, United Kingdom, [4]Wellcome Trust Sanger Institute, Cambridge, United Kingdom, [5]University of Cambridge, Cambridge, United Kingdom

The West African Ebola epidemic was the first emerging outbreak in which near real-time sequencing was available. Novel phylogenetic methods can determine transmission events, but have not previously been used in emerging outbreaks. Thus, the value of such data for outbreak investigation remains unclear. We use data from the Ebola outbreak in Sierra Leone (SL) to illustrate how incorporating genomic data with traditional epidemiological analyses provides additional insight, with potential to inform interventions and limit cases. We used routinely collected outbreak data linked to Ebolavirus (EBOV) genome sequences. A phylogeny of 554 EBOV sequences from SL was reconstructed by maximum-likelihood inference from which transmission clusters were identified. We focused on an isolated outbreak of Ebola in a rural village

(64 cases, 41 sequences) and inferred a 'sequence based transmission tree' (SBTT) using Outbreaker package. The conclusions were compared to those drawn from the traditional epidemiological investigation. Sequence based analysis confirmed the traditional epidemiological findings with respect to the origins and sources of this outbreak- a single introduction via the same index case. However, the SBTT was inconsistent with the epidemiological hypothesis of parent to child transmission. Sequences for several children clustered together and were directly related to the index case despite no contact. Combined with field reports this suggested children may have been infected by playing in puddles contaminated with Ebolavirus after a traditional healing ceremony, a previously unrecognised transmission route. To our knowledge, this is the first time molecular methods have detected a potential novel mechanism of transmission, not identified via traditional epidemiological surveillance. Thus, sequence data, where possible, should be incorporated into standard outbreak investigation. This combined approach is likely to enhance understanding of transmission dynamics, which allows faster and more effectively targeted interventions, thus limiting the impact of infectious disease outbreaks.

IMPROVING CROSS-BORDER AND REGIONAL COMMUNICABLE DISEASE SURVEILLANCE AND RESPONSE THROUGH A NOVEL MULTICOUNTRY COLLABORATION, TOGO, BENIN, NIGERIA, AND CAMEROON

Clement Kakai Glele[1], Mahmood Dalhat[2], Ouyi Tante Valenin[3], Elisabeth Betsi Dibongue[4], Elvira McIntyre[5], Patrick Nguku[2], Godjedo Togbemabou Primous Martial[1], Rodrigue Kohoun[1], Nestor D. Noudeke[6], Dibog Luc Bertrand[4], Amabo Chi Franck[4], Armelle Ngomba[4], Tamekloe Tsidi Agbeko[3], Chikwe Iheakweazu[7], **Rebecca D. Merrill**[8]

[1]Ministry of Health, Cotonou, Benin, [2]African Field Epidemiology Network, Nigeria Field Epidemiology and Laboratory Training Program, Abuja, Nigeria, [3]Ministry of Health, Lome, Togo, [4]Ministry of Public Health, Douala, Cameroon, [5]Booze Allen Hamilton, Atlanta, GA, United States, [6]African Field Epidemiology Network, Benin Field Epidemiology Training Program, Cotonou, Benin, [7]Nigeria Centre for Disease Control, Abuja, Nigeria, [8]Centers for Disease Control and Prevention, Atlanta, GA, United States

In environments with strong transborder community connectivity and population movement, local disease outbreaks can quickly impact two or more countries. Establishing and strengthening binational and regional public health collaboration is a critical step in improving preparedness and response capacity to mitigate international spread of a communicable disease. The Ministries of Health in Togo, Benin, Nigeria, and Cameroon initiated a collaboration, in partnership with the US CDC Division of Global Migration and Quarantine, to analyze national cholera surveillance data to inform evidence-based recommendations for collaborative national, binational, and regional surveillance policies and response strategies to mitigate cross-border spread of future cholera outbreaks. Collaborators created a data set of all 33,451 confirmed and probable cholera cases from 2010 and from Togo and Benin in 2011 (n=75 [Togo 2010], 30 [Togo 2011], 62 [Benin 2010], 779 [Benin 2011], 21,111 [Nigeria 2010], 11,394 [Cameroon 2010]) to identify consistencies in data management approaches and spatial patterns in outbreak progression. All countries reported case information by at least administrative levels 1 and 2, similar to US state and county, and reported or could calculate the aggregate number of cases and deaths by epidemiological week. Inconsistencies in epidemiologic week definitions were rectified through consensus and data cleaning. Collaborators applied the results to create data management strategies that will facilitate cross-border surveillance data sharing during response activities in future outbreaks. For example, they defined a common, minimum list of variables and their definitions to include in an investigation for an outbreak with risk of cross-border transmission. Through this innovative, multicountry partnership, which will expand to analyze cholera data from 2011 to the present, Ministries of Health are strengthening cross-border collaboration and contributing to improved global health security against communicable disease threats.

Boston, MA, United States, [8]Center for Innovation in Global Health, Stanford University School of Medicine, Stanford, CA, United States

Nomadic pastoralists are among Sub-Saharan Africa's poorest, hardest-to-reach, and least-served populations. Pastoralist communities are notoriously difficult to survey due to factors including their high degree of mobility, the remote terrain they inhabit, fluid domestic arrangements, and cultural barriers. Current sampling methodologies do not adequately capture the demographic and health parameters of nomadic populations and as a result, mobile pastoralists are often "invisible" in population data such as national censuses and the Demographic and Health Surveys (DHS). We developed methodology combining remote sensing and geospatial analysis to enumerate seasonal pastoralist encampments in southwest Ethiopia with the goal of demonstrative the effective use of an alternative sampling frame to collect representative data on a mobile population. Using a sampling frame constructed based on geospatial data, we conducted a survey focused on Maternal and Child Health (MCH) - a domain highlighted in the Key Indicator Report of the 2016 Ethiopian DHS - using standardized instruments from the DHS questionnaires. Our field validation suggests that the methodology used in this study is a logistically feasible alternative to conventional census-based sampling frames. Surveying 347 women of reproductive age, we found substantial disparities between the nomadic pastoralist populations in our sample compared to DHS-derived country estimates in key maternal and child health indicators such as antenatal care, skilled birth attendance, and vaccination coverage. We draw comparisons between numerous MCH indicators among this population and national data, highlighting unique characteristics of the study population that hold key relevance to designing health interventions. We propose the use of alternative geospatial sampling frames in pastoralist regions to reduce under-coverage and prevent bias in national data. Implementing effective methodology for the health surveillance of mobile populations is a crucial step towards developing health systems for these underserved groups.

2097

COMMUNITY HEALTH VOLUNTEERS TRAINED VIA U.S. AGENCY FOR INTERNATIONAL DEVELOPMENT (USAID)/ PRESIDENT'S MALARIA INITIATIVE (PMI) PARTNERS RAPIDLY RESPOND TO A PNEUMONIC PLAGUE OUTBREAK, MADAGASCAR, 2017

Dr Jocelyn Razafindrakoto[1], Dr Laurent T. Kapesa[1], Dr Andry Rahajarison[2], Lova Ralijaona[2], Dr Herly Ramiandrisoa[3], Dr Riana Ramanantsoa[4], Catherine Dentinger[5]

[1]U.S. Agency for International Development/PMI, Antananarivo, Madagascar, [2]U.S. Agency for International Development Health Population Nutrition, Antananarivo, Madagascar, [3]U.S. Agency for International Development Community Capacity for Health Program, Antananarivo, Madagascar, [4]U.S. Agency for International Development Mikolo project, Antananarivo, Madagascar, [5]Centers for Disease Control and Prevention/PMI, Antananarivo, Madagascar

Human plague is endemic in Madagascar; approximately 400 cases are reported annually, most of which are bubonic disease. In late August 2017, an outbreak of pneumonic disease began in the capital city and one other urban center and spread to surrounding districts. Following a Ministry of Health (MOH) request, Community Health Volunteers (CHV) previously trained by USAID and PMI partners to provide basic health services in 6,726 Fokontany (smallest administrative unit), rapidly responded. The outbreak, which eventually totaled 2,158 cases and 174 deaths, was declared over on November 27, 2017. We describe efforts of USAID/PMI's partners to improve community-based health services via trained CHVs, and how these CHVs were quickly trained and equipped for the plague response. Within two weeks of the MOH's declaration of an outbreak in early October, 2017, USAID/PMI partners mobilized the CHVs they support. Partners used existing channels to distribute educational messages and outbreak tools developed by the MOH and the World Health Organization. They trained 440 CHVs based in plague-affected areas using an existing cascade-training infrastructure to teach CHVs to perform response activities. CHVs detected and referred 457 suspected plague cases and traced and referred for post-exposure prophylaxis 3,924 of the 7,270 (54%) case contacts reported during the outbreak. CHVs also led community hygiene campaigns to decrease rat infestations, provided door-to-door information to residents regarding plague prevention and prompt care seeking, chaired community awareness meetings, and distributed 30,000 educational tool kits. CHVs reached an estimated 430,000 persons during the response. Training and supporting CHVs to provide basic health services via PMI and USAID partners in rural communities in Madagascar resulted in a cadre of providers capable of responding to a public health emergency. The efforts of Malagasy CHVs likely contributed to limiting the magnitude and duration of the 2017 pneumonic plague outbreak.

IDENTIFICATION OF ENTERIC PATHOGEN RESERVOIRS AND TRANSMISSION PATHWAYS ASSOCIATED WITH CHILDHOOD GROWTH IN THE URBAN INDIAN, AND RURAL BANGLADESH SITES OF THE GLOBAL ENTERIC MULTICENTER STUDY

Kurt Z. Long[1], Abu S. Faruque[2], Chris Stride[3], Inong R. Gunanti[1], Johanna Sanchez[4], Salvador Zamora[5], Georgina Mora[6], James P. Nataro[7], Dilruba Nasrin[8], Myron Levine[8], Karen Kotloff[9]

[1]Swiss Tropical and Public Health Institute, Basel, Switzerland, [2]International Centre for Diarrhoeal Disease Research, Bangladesh, Dhaka, Bangladesh, [3]The Institute of Work Psychology, University of Sheffield, Sheffield, United Kingdom, [4]Child Health Research Centre, Faculty of Medicine and Biomedical Sciences, University of Queensland, Brisbane, Australia, [5]Mathematics Department, UNAM, Mexico City, Mexico, [6]Secretariat of Health, Xalapa, Mexico, [7]Department of Pediatrics, University of Virginia School of Medicine, Charlottesville, VA, United States, [8]Department of Medicine, University of Maryland School of Medicine, Baltimore, MD, United States, [9]Department of Pediatrics, University of Maryland School of Medicine, Baltimore, MD, United States

The burden of childhood growth impairment remains high in many South Asian communities and the region as a whole. Identification of causal pathways linking enteric pathogen reservoirs and transmission with childhood growth in different community settings can aid in the development of more effective intervention strategies to reduce this burden. Structural equation models (SEM) were developed separately for the Bangladeshi, and Indian components of the Global Enteric Multicenter Study (GEMS) to model effects of potential household pathogen transmission pathways on growth measures in rural and urban communities. Models were developed to test whether pathogen reservoirs were associated directly with height-for-age z-scores (HAZ) or were indirectly mediated by enteric infections. Tests also determined whether hygiene behaviors and maternal education moderate associations of pathogen reservoirs with infections and subsequently HAZ. A total of 3,582 children were enrolled in Kolkata, India and 3,859 enrolled in Mirzapur, Bangladesh. In India, unimproved toilet facilities had an indirect negative association with HAZ mediated by *Giardia* infections. Handwashing before nursing reduced this negative effect through the elimination of the positive association of unimproved facilities with *Giardia*. Stored water was negatively associated with HAZ but treating water reversed this effect. In Bangladesh, fuel dung use, unimproved toilet facilities and unsafe child feces disposal had negative indirect associations with HAZ via both *Cryptosporidium* and *Giardia* infections. Specific handwashing behaviors and maternal education reduce this association via the elimination of these protozoan infections. In conclusion, household pathogen reservoirs and corresponding pathways incorporating *Giardia* and *Cryptosporidium* infections are qualitatively different between urban and rural sites. Greater reductions in growth impairment may be achieved in South Asia through the development of targeted public health interventions for rural and urban communities using indicators of the unique pathways found in each of these settings.

2099

DEVELOPING A PUBLIC HEALTH TOOL TO MONITOR THE TRANSMISSION POTENTIAL OF NIPAH VIRUS DURING OUTBREAKS

Birgit Nikolay[1], Henrik Salje[1], Hossain M. Sazzad[2], Meerjady Sabrina Flora[3], Stephen P. Luby[4], Simon Cauchemez[1], Emily S. Gurley[5]

[1]Institut Pasteur, Paris, France, [2]International Centre for Diarrhoeal Disease Research, Bangladesh, Dhaka, Bangladesh, [3]Institute of Epidemiology Disease Control and Research, Dhaka, Bangladesh, [4]Stanford University, Stanford, CA, United States, [5]Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States

In Bangladesh, human Nipah virus (NiV) infections have been reported almost every year since 2001 with regular person-to-person transmission events. With a case fatality of >70% and no available treatments or vaccines, NiV was identified by the World Health Organization as one of nine pathogens that pose the highest risk for large-scale outbreaks. Prompt identification of changes in the transmission potential or the clinical presentation of cases is important so that public health responses can be deployed efficiently. We present a tool that allows public health officials to identify significant changes in a set of key transmission and case characteristics including (i) the annual number of spillovers from the bat reservoir, (ii) the proportion of cases who transmit to others, (iii) the reproduction number and (iv) the case fatality rate. We investigated how these measures changed over time based on all cases identified since systematic hospital-based surveillance began in 2007 to 2014 and explored differences in outbreak patterns before 2007. From 2001 - 2007, 18 spillovers were detected with a mean of 3 per year (95%CI 0.8-11). From 2007-2014, after systematic surveillance began, 61 spillovers were detected. The mean number of annual detected spillovers increased from 2.7 (95%CI 1.3-5.4) in 2007-2009 to 10.6 (95%CI 7.9-14) in 2010-2014. By contrast, the proportion of cases who transmitted (11%, 95%CI 6-18), the reproduction number (0.2, 95%CI 0.1-0.5) and the case fatality rate among primary (91%, 95%CI 84-96) or secondary cases (46%, 95%CI 29-63) did not change significantly over the period of stable surveillance. The person-to-person transmission potential of NiV appears stable since start of systematic surveillance and public health officials should be able to detect significant departures from this baseline in future outbreaks using the tool. Increases in detected spillovers over time could represent year-to-year variation in infections in the reservoir host. Systematic surveillance of NiV has allowed the establishment of baseline trends and will be essential to monitor changes in transmissibility to prevent large outbreaks.

RDHS: AN R PACKAGE TO INTERACT WITH THE DEMOGRAPHIC AND HEALTH SURVEYS (DHS) PROGRAM DATA SETS

Oliver J. Watson, Jeff W. Eaton

MRC Centre for Global Infectious Disease Analysis, Imperial College London, London, United Kingdom

The Demographic and Health Surveys (DHS) Program has collected and disseminated population survey data from over 90 countries for over 30 years. In many countries, DHS provide the key data that mark progress towards targets such as the Sustainable Development Goals (SDGs) and inform health policy such as detailing trends in child mortality and characterising the distribution of use of insecticide-treated bed nets in Africa. Though standard health indicators are routinely published in survey final reports, much of the value of DHS is derived from the ability to download and analyse standardized microdata datasets for subgroup analysis, pooled multi-country analysis, and extended research studies. We have developed an open-source freely available R package '*rdhs*' to facilitate management and processing of DHS survey data. The package provides a suite of tools to (1) access standard survey indicators through the DHS Program API, (2) identify all survey datasets that include a particular topic or indicator relevant to a particular analysis, (3) directly download survey datasets from the DHS website, (4) load datasets and data dictionaries into R, and (5) extract variables and pool harmonized datasets for multi-survey analysis. The suite of tools within the package represents the output of conversations with numerous research groups globally, and serves to simplify commonly required analytical pipelines. The end result aims to increase the end user accessibility to the raw data and create a tool that supports reproducible global health research. We detail the core functionality of *rdhs* by demonstrating how the package can be used to identify heterogeneity in malaria rapid diagnostic test (RDT) false negative rates (FNR) in Africa, and the association between malaria prevalence and RDT FNR. Using *rdhs* we extracted paired microscopy and RDT results for 216,587 children under the age of 5 from 22 African countries from 2008-2016. We identified a significant association between RDT FNR and malaria prevalence (OR = 0.31, 95% CI = 0.23-0.42, p<0.001), which gives support for utilising high sensitivity RDTs in lower transmission settings.

IMPACT OF INDOOR RESIDUAL SPRAYING IN REDUCING MALARIA CASES IN RWANDA, 2013-2017

Emmanuel Hakizimana[1], Dunia Munyakanage[1], Emily Piercefield[2], Monique Murindahabi[1], Aline Uwimana[1], Didier Uyizeye[1], Erin Eckert[3], Kaendi Munguti[4], Peter Obenauer[5], Aimable Mbituyumuremyi[1]

[1]Rwanda Biomedical Center, Malaria and Other Parasitic Diseases Division, Kigali, Rwanda, [2]US President's Malaria Initiative, Malaria Branch, Division of Parasitic Diseases and Malaria, US Centers for Disease Control and Prevention, Kigali, Rwanda, [3]US President's Malaria Initiative, United States Agency for International Development, Bureau for Global Health, Office of Health, Infectious Diseases, and Nutrition, Washington, DC, United States, [4]US President's Malaria Initiative, United States Agency for International Development, Kigali, Rwanda, [5]Navy and Marine Corps Public Health Center Detachment-CDC, Centers for Disease Control and Prevention, Entomology Section, Atlanta, GA, United States

Indoor residual spraying (IRS) is a core malaria prevention tool along with insecticide treated nets (ITNs). In 2013, 83% of Rwanda households owned ≥1 ITN; and during 2013–2016, Rwanda conducted IRS twice yearly in 3–5 districts. From 2012 baseline to 2017, national malaria cases increased >8-fold, but malaria burden from 5 districts receiving IRS at least twice decreased from 57.6% of national confirmed malaria cases to 18.8%. To better understand IRS impact, we calculated percentage change in number of new confirmed malaria cases for sprayed districts in 12 months following each spray round compared with the prior 12 months. With resource constraints, districts were not always fully covered by IRS. For districts with full coverage, combined malaria cases decreased 31.4% in the 12 months after IRS (range: -79.5% to 137.3%; median: -26.5%). For spray rounds targeting <50% of a district, combined malaria cases increased 75.4% (range: -32.3% to 516.6%; median 63.8%), similar to the 87.7% median annual case increase among districts not receiving IRS. In one district, cases declined 79.1% (late 2014) and 6.2% (early 2015) after full-district IRS, but withdrawal of IRS from nearly 70% of the district late 2015 was followed by a 283.6% increase in cases; resumption of full-district IRS in 2016 slowed case increase to 24.0% from the 12 months prior. Delay implementing IRS by one month for the early 2016 rainy season in 2 districts was followed by a combined 70.8% increase in cases compared with a 43.4% decrease in cases for 2 districts using the same insecticide one month earlier. Malaria cases increased 50.1% after IRS using a pyrethroid class insecticide compared with reductions in malaria cases after IRS with carbamate and organophosphate of 8.0% and 56.3%, respectively. Impact of carbamate diminished over time from 18.1% decrease in malaria cases during initial 2 years of use to 3.5% decrease in cases thereafter, likely related to detected resistance. IRS appears to

decrease malaria burden in Rwanda, but IRS impact can be optimized by sustained full-district coverage, appropriate seasonal timing, and rotation of insecticide class to mitigate resistance.

RAPID IMPROVEMENTS TO RURAL UGANDAN HOUSING AND THEIR ASSOCIATION WITH MALARIA FROM INTENSE TO REDUCED TRANSMISSION: FINDINGS FROM A COHORT STUDY

John Rek[1], Victor Alegana[2], Emmanuel Arinaitwe[1], Ewan Cameron[3], Moses Kamya[4], Agaba Katureebe[1], Steve W. Lindsay[5], Maxwell Kilama[1], Sarah G. Staedke[6], Jim Todd[7], Grant Dorsey[8], Lucy S. Tusting[3]

[1]Infectious Diseases Research Collaboration, Kampala, Uganda, [2]University of Southampton, Southampton, United Kingdom, [3]Oxford Big Data Institute, Li Ka Shing Centre for Health Information and Discovery, Nuffield Department of Medicine, University of Oxford, Oxford, United Kingdom, [4]Department of Medicine, Makerere University College of Health Science, Kampala, Uganda, [5]Department of Biosciences, Durham University, Durham, United Kingdom, [6]Department of Clinical Research, London School of Hygiene & Tropical Medicine, London, United Kingdom, [7]Department of Population Health, London School of Hygiene & Tropical Medicine, London, United Kingdom, [8]Department of Medicine, University of California, San Francisco, CA, United States

Improving housing presents a promising opportunity for malaria control by reducing indoor exposure to mosquitoes. We measured recent changes in house design in rural Uganda and evaluated their association with malaria in relation to a mass scale-up of control efforts. This analysis was part of a cohort study designed to estimate longitudinal changes in key malaria metrics. All children aged 6 months to 10 years (n=384) living in 107 households in Nagongera sub-country, Tororo, Uganda, were given long-lasting insecticide-treated nets and followed between Aug 19, 2011, and June 30, 2017. Repeat rounds of indoor residual spraying (IRS) of insecticide were initiated on Dec 5, 2014. Socioeconomic data were collected at two timepoints (Sept 25-Oct 9, 2013 and June 21-July 11, 2016) and houses were classified as modern or traditional. Associations between house design and human biting; parasite prevalence; and malaria incidence were evaluated before and after the introduction of IRS: For all analyses, the P-values were less than 0.004. The implementation of IRS was associated with significant declines in human biting rate (33·5 vs 2·7 Anopheles per house per night after IRS), parasite prevalence (32·0% vs 14·0%), and malaria incidence (3·0 vs 0·5 episodes per person-year at risk). The prevalence of modern housing increased from 23·4% in 2013 to 45·4% in 2016. Compared with traditional houses, modern houses were associated with a 48% reduction in human biting rate before IRS (adjusted incidence rate ratio [aIRR] 0·52, 95% CI 0·36-0·73), and a 73% reduction after IRS (aIRR 0·27, 0·17-0·42). Before IRS, there was no association between house type and parasite prevalence, but after IRS there was a 57% reduction in the odds of parasitemia in modern houses compared with traditional houses, controlling for age, sex, and socioeconomic position (adjusted odds ratio 0·43, 95% CI 0·24-0·77). House type was not associated with malaria incidence before or after IRS. Improved housing in rural Uganda and was associated with additional reductions in mosquito density and parasite prevalence following the introduction of IRS.

2103

THE IMPACT OF MULTIPLE ROUNDS OF INDOOR RESIDUAL SPRAYING ON MALARIA INCIDENCE AND HEMOGLOBIN LEVELS IN A HIGH TRANSMISSION SETTING

Kate Zinszer[1], Deepa Jahagirdar[2], John Rek[3], Emmanuel Arinaitwe[3], Joaniter Nankabirwa[3], Moses Kamya[4], Isabel Rodriguez-Barraquer[5], Bryan Greenhouse[5], Grant Dorsey[5]

[1]University of Montreal, Montreal, QC, Canada, [2]McGill University, Montreal, QC, Canada, [3]Infectious Disease Research Collaboration, Kampala, Uganda, [4]Makerere University of College of Health Sciences, Kampala, Uganda, [5]University of California San Francisco, San Francisco, CA, United States

Malaria is the leading cause of morbidity and mortality in Uganda, with some of the highest levels of malaria transmission intensity in the world. Indoor residual spraying (IRS) is an important control intervention used in targeted areas in Uganda. The objective of this study was to estimate the effect of IRS activity, including the longevity of its effect, on malaria incidence and hemoglobin levels in a cohort of children in Nagongera, Uganda. A dynamic cohort of children was enrolled in Nagongera, Uganda starting in 2011. Household were randomly selection from enumeration surveys and all eligible children aged 0.5-10 year olds enrolled from 107 households. Malaria was diagnosed using passive surveillance and defined as a fever and the detection of parasites by microscopy. The first three rounds of IRS utilized a carbamate (bendiocarb) approximately every six months and a fourth round utilized an organophosphate (pirimphos-methyl) with plans to administer every 12 months. The analysis included data through June 20, 2017 and Poisson generalized linear model with a log link function. There were 384 children with 2,874 incident episodes of malaria and an average of 2.0 episodes per year per person over the entire study period. The number of incident malaria episodes per person year after the implementation of IRS was reduced by 79% with the age at first episode of malaria increasing to 6 years old from 4.8 years pre-IRS. Hemoglobin levels significantly increased by 11% by IRS round 4 and by over 1 g/dL, when compared to pre-IRS levels. The largest reductions in malaria occurred within the first two to seven weeks of IRS implementation, coinciding with high household coverage. A rebounding of cases occurred several weeks after the spraying round finished, with large variation between the rounds. We also found that larger households were associated with a larger reduction following IRS compared to smaller households. Our study supports the policy recommendation of IRS usage in a perennial transmission area to rapidly reduce the transmission and also that the most significant reductions in incidence were observed when high household coverage was obtained.

2104

INTERMITTENT PREVENTIVE TREATMENT OF MALARIA IN PREGNANCY AND BIRTH OUTCOMES: ASSESSMENT OF THE FIVE DOSE SULFADOXINEPYRIMETHAMINE POLICY IN RURAL NORTHERN GHANA

Abraham Oduro[1], Ibrahim Agongo[2], Victor Asoala[1], Francis Anto[2]

[1]Navrongo Health Research Centre, Navrongo, Ghana, [2]University of Ghana, Accra, Ghana

Intermittent preventive treatment of malaria in pregnancy with sulfadoxine-pyrimethamine (IPTpSP) decreases placental parasitaemia and improves birth outcomes. Ghana based on the WHO current recommendation administers five doses of SP given during antenatal care to pregnant, spaced one month apart after 16 weeks of gestation till delivery. This study determined the level of uptake of the five-dose SP policy and its association with birth outcomes in rural northern Ghana. A hospital-based study was carried out among nursing mothers who had delivered within ten weeks and were seeking postnatal care at the district Hospital. Antenatal data on first ANC, number of visits, receipt of IPTp-SP and birth outcomes were documented. Mothers were interviewed on socio-demographic characteristics and obstetric history. Bivariate and multivariate analyses determined association between antenatal indicators, uptake of IPTpSP and birth outcomes. The proportion of uptake of three to five doses of SP were: IPT3 (76.4%), IPT4 (37.3%) and IPT5 (16.0%). The proportions of women who received first dose of SP at 16, 17-24 and 25-36 weeks gestation were: 16.9%, 56.7% and 26.4% respectively. Women who took the first dose of SP during the second trimester were more likely to receive ≥3 doses of SP than those who took the first dose during the third trimester ($\chi 2 = 60.1$, $p<0.001$). Women who made ≥4 visits were more likely to receive ≥3 doses of SP than those who made <4 visits ($\chi 2 = 87.6$, $p<0.001$). A higher proportion (82.5%, 95% CI: 76.4-87.5) of

mothers who took ≥3 doses of SP delivered at term compared to 61.7% (95% CI: 48.2-73.9) of those who took <3 doses (p = 0.001). Similarly, 88.1% (95% CI: 82.7-92.7) of mothers who took ≥3 doses of SP gave birth to babies weighing ≥2.5 kg compared to 61.7% (95% CI: 49.9-75.4) of those who took <3 doses of SP (p <0.001). Uptake of five doses of SP (new Ghana policy) was very low. Increased efforts towards improving early ANC attendance could increase uptake of SP and improve pregnancy outcomes.

2105

IMPACT OF INTERMITTENT PREVENTIVE TREATMENT OF MALARIA IN PREGNANCY WITH MONTHLY DIHYDROARTEMISININ-PIPERAQUINE ON THE INCIDENCE OF MALARIA DURING INFANCY

Abel Kakuru[1], Sarah Staedke[2], Daniel Chandramohan[2], Richard Kajubi[1], Teddy Andra[1], Harriet Adrama[1], Miriam Nakalembe[3], Tamara D. Clark[4], Theodore Ruel[4], Prasanna Jagannathan[5], Diane V. Havlir[4], Moses R. Kamya[3], Grant Dorsey[4]

[1]Infectious Diseases Research Collaboration, Kampala, Uganda, [2]London School of Hygiene & Tropical Medicine, London, United Kingdom, [3]Makerere University College of Health Sciences, Kampala, Uganda, [4]University of California San Francisco, San Francisco, CA, United States, [5]Stanford University, San Francisco, CA, United States

Malaria in pregnancy has been associated with an increased risk of malaria during infancy in observational studies. However, evidence from controlled trials on the impact of intermittent preventive treatment in pregnancy (IPTp) on malaria during infancy is limited. We compared the incidence of malaria among infants born to women enrolled in a double-blinded randomised controlled trial where monthly IPTp with dihydroartemisinin-piperaquine (DP) was found to be far superior to sulfadoxine-pyrimethamine (SP) for the prevention of malaria during pregnancy in a high transmission setting in Uganda. Children are being followed for all of their health care needs through 12 months of age with malaria diagnosed as fever and a positive blood smear by microscopy using passive surveillance. Of 674 live births with at least 1 day of follow-up, 336 were born to mothers randomised to monthly IPTp-SP and 338 born to mothers randomised to monthly IPTp-DP. Follow-up of infants is ongoing and here we present preliminary results through February 2018, which includes a total of 624 episodes of malaria and 440 person years of follow-up. Between birth and 3 months of age the incidence of malaria has been relatively low and similar between children born to mothers who received IPTp with DP compared to SP (0.64 vs 0.69 episodes PPY, p=0.71). After 3 months of age, the incidence of malaria is 20% lower among children born to born to mothers who received IPTp with DP compared to SP (1.64 vs 2.07 episodes PPY, p=0.048). This protective effect was greatest among children born to primigravid mothers where after 3 months of age, the incidence of malaria is 37% lower among children born to born to mothers who received IPTp with DP compared to SP (1.44 vs 2.29 episodes PPY, p=0.04). In summary, monthly IPTp with DP was superior to SP for the prevention of malaria during pregnancy in a high transmission setting of Uganda and appears to have the added benefit of reducing the incidence of malaria during infancy, especially among children born to mothers who were pregnant for the first time. It is anticipated that near final results of this study will be available at the time of the ASTMH meeting.

2106

SEASONAL MALARIA CHEMOPREVENTION, AN EFFECTIVE INTERVENTION FOR REDUCING MALARIA MORBIDITY AND MORTALITY

Moumouni Bonkoungou[1], Ousmane Badolo[1], Stanislas Nebie[1], Justin Tiendrebeogo[1], Mathurin Dodo[1], Thierry Ouedraogo[1], Youssouf Sawadogo[1], Danielle Burke[2], Bethany Arnold[2], William Brieger[3], Gladys Tetteh[2]

[1]Jhpiego, Ouagadougou, Burkina Faso, [2]Jhpiego, Baltimore, MD, United States, [3]Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States

Malaria remains the leading cause of morbidity (43.4% of reasons for consultation in 2016) and mortality (21.8% of deaths in 2016) in Burkina Faso; the heaviest burden being amongst children under 5 and pregnant women. Since 2013, Jhpiego, has implemented the Improving Malaria Care project (IMC) funded by PMI, in collaboration with the National Malaria Control Program of Burkina Faso. In 2017, IMC supported the implementation of the Seasonal Malaria Chemoprevention (SMC) campaign in Boromo and Dano health districts, as part of a larger national campaign carried out in 59 districts. SMC consists of administration of up to 4 monthly doses of a full treatment course of co-packaged Amodiaquine, Sulfadoxine + Pyrimethamine to all eligible children aged 3-59 months during the high malaria transmission season. The objective is to maintain therapeutic antimalarial medicine concentrations in the blood during the period of greatest risk. There were 58,246 children treated in the Boromo Health District and 50,007 at Dano during the 2017 campaign, representing 97.3% of the target population. IMC for its part in the campaign covered 3.6% of all children in the country. At Boromo, between 2016 and 2017, there was a decrease in cases of severe malaria by 16.6% (3900 to 3252) in the general population and by 25.4% (2057 to 1535) in children under 5. The number of malaria deaths in children under 5 also declined by 64.4% (45 to 16) between 2016 and 2017. In Dano, a reduction in severe malaria cases of 5.62% (4392 to 4145) and 26.4% reduction in deaths (53 to 39) was observed among children under 5 during the same period. Key challenges were: i) inability to conduct rapid assessment to measure coverage, ii) insufficient number of health staff for community distributors' supervision area, iii) access to some villages due to the rainy season iv) unknown adherence to drug administration during 2nd and 3rd doses. SMC appears to be an effective strategy in these districts for the reduction of cases of severe malaria-related illness and deaths in children under the age of 5. To better organize future SMC campaigns, the challenges identified during this campaign should be addressed.

2107

NEAR REAL-TIME REPORTING THROUGH DHIS2 TO DRIVE EFFICIENCY DURING LLIN MASS DISTRIBUTION CAMPAIGNS: LESSONS FROM KINSHASA, DRC, AND MALI

Cedric Mingat[1], Njara Rakotonirina[2], Olivier Palata[2], Anthony M'vemba[2], Riddy Ndoma[2], Christina Lussiana[3], Bram Piot[4], Joseph Lewinski[4]

[1]Population Services International, Bamako, Mali, [2]Association de Santé Familiale, Kinshasa, Democratic Republic of the Congo, [3]Population Services International, Nairobi, Kenya, [4]Population Services International, Washington, DC, United States

Mass distribution campaigns of Long Lasting Insecticidal Nets (LLINs) are an intense effort and pose operational challenges, such as household (HH) registration for correct LLIN allocation and management of stock balances between LLIN needs and quantities distributed. In order to overcome these challenges, Population Services International (PSI) developed and used an innovative monitoring tool in DHIS2 to collect data on two critical phases of the LLIN campaign: allocation of nets during registration and their distribution. PSI piloted the use of the DHIS2 LLIN Distribution monitoring tool during the LLIN mass campaign in Kinshasa, DRC, in October 2016

and in Kayes region, Mali, in December 2017. A total of 4,964,938 and 1,437,111 nets were distributed and tracked in DHIS2 in almost real time in Kinshasa province and Kayes region, respectively. Key performance indicators monitored in DHIS2 include: number of HHs by distribution site and size, number of LLINs allocated by distribution site, number of LLINs received by distribution site, number of LLINs distributed by distribution site, and percentage of LLINs distributed out of LLINs received by distribution site. This innovation in the collection and management of LLIN distribution data reduces the long duration of data compilation and validation and improves the efficiency and effectiveness in activity monitoring, as well as stock management. Rapid access to information by all health authorities involved in the campaigns facilitated quick detection of inconsistencies and timely decision-making. In terms of challenges, the issue of poor or unstable telephone network coverage and lack of power supply in very remote areas have sometimes affected data entry and data syncing with DHIS2. The benefits of this innovative approach overcame these challenges and, as advocated by Dr. Joris Likwela Losimba, NMCP Director in DRC, the use of the DHIS2 LLIN Distribution tool is an excellent way of managing future mass campaigns. When used within the national management information system, it also contributes to strengthening the health system and can be used for other related areas.

2108

THE PREDICTORS OF HEALTH WORKER PRACTICES IN LOW- AND MIDDLE-INCOME COUNTRIES: A SYSTEMATIC REVIEW

Alexander K. Rowe[1], Samantha Y. Rowe[1], David H. Peters[2], Kathleen A. Holloway[3], John Chalker[4], Dennis Ross-Degnan[5]

[1]Centers for Disease Control and Prevention, Atlanta, GA, United States, [2]Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, United States, [3]University of Sussex, Brighton, United Kingdom, [4]Management Sciences for Health, Arlington, VA, United States, [5]Harvard Medical School, Boston, MA, United States

Health worker (HW) performance in low- and middle-income countries (LMICs) is often inadequate. Understanding the factors that influence HW performance is useful for anticipating where there might be quality problems and designing studies to test strategies to improve performance. To identify contextual and methodological predictors of HW practice outcomes expressed as a percentage (eg, % of patients treated correctly), we used random-effects linear regression modeling to analyze pre-intervention results from a systematic review on improving HW performance in LMICs. We searched 47 databases for published studies and 52 document inventories for unpublished studies up to early-2016. We screened 209,887 citations and identified 322 eligible studies for this analysis. These studies included 1,938 measures of HW practices. Mean performance was low, at 40.1% across all outcomes. The final model, which included all of the following factors, found that for every $1000 increment in gross national income, performance was 1.7 percentage-points (%-points) lower ($p = 0.02$). Performance in Europe and the Middle East was 10.3 %-points higher than in Asia ($p = 0.04$), with no differences for other continents. Performance in private health facilities was 8.3 %-points lower than in public facilities ($p = 0.03$). Compared to practice outcomes for multiple health conditions (eg, % of all patients receiving injections), performance was lower for specific acute and chronic diseases (–7.6 and –8.8 %-points, respectively, $p < 0.02$), but not for pregnancy. Compared to treatment outcomes, performance was 9–11 %-points lower for patient assessment, counseling, referral, and documentation ($p < 0.03$). Performance was 8.2 %-points lower in studies using patient interviews ($p = 0.005$), with no differences for other methods (eg, chart review). We found no differences between HW types and no evidence of a secular trend from 1990–2015. Selection bias was an important potential limitation. In conclusion, many factors were associated with HW practices. The results could help target quality improvement efforts and inform research on improving HW performance in LMICs.

EQUITABLE BUT NOT PRO-POOR CHANGE IN MATERNAL AND NEWBORN HEALTH

Tanya Marchant, Emma Beaumont, Nasir Umar, Della Berhanu, Meenakshi Gautham, Elizabeth Allen, Joanna Schellenberg

London School of Hygiene & Tropical Medicine, London, United Kingdom

Health disparities persist in maternal and newborn health (MNH) with poorer families receiving less and lower quality care than wealthier families. To close this gap, many large-scale programmes have focused on pro-poor approaches to providing care. We present population level evidence on the equity of changes in MNH care from three high mortality settings where large-scale, community-based interventions were put in place: Gombe State in north-east Nigeria, Ethiopia, and the State of Uttar Pradesh in India. In each setting household surveys were carried out in 2012 amongst 7000, 3000 and 8500 women respectively, with follow-up data collection in 2015. The same survey methods were applied each time. Principle components analysis was used to determine socio-economic status (SES). Nine common indicators were identified as being targeted across the settings: four contacts (antenatal, delivery and postnatal care for mothers and newborns) and five interventions (handwashing and use of gloves by birth attendants, and clean cord care, early breastfeeding and thermal care of the newborn). At baseline, coverage was inequitable for all indicators with the poorest families consistently having lowest coverage. Different indicators showed improvement between settings but where changes did occur they were exclusively equitable in that coverage increased for all SES groups equally. However, because of the pre-existing inequity this meant that changes were not pro-poor and coverage remained unanimously inequitable. For example, handwashing with soap by delivery attendants increased between 2012-2015 from 55% to 81% in Gombe State (p-value <0.001). In 2012 the odds ratio of coverage between richest and poorest was 1.5 (95% confidence interval 1.2-1.9) and in 2015 it was again 1.5 (1.3-1.7). And the p-value for the likelihood ratio test for the interaction between time and SES was 0.84 indicating no evidence that indicator coverage between 2012 and 2015 differed by SES. Results across these settings are examined with reflection on findings from other disease control initiatives that have been designed for pro-poor change.

2110

THE RELATIVE IMPORTANCE OF FINANCIAL AND NON-FINANCIAL INCENTIVES FOR COMMUNITY HEALTH WORKERS: EVIDENCE FROM A DISCRETE CHOICE EXPERIMENT IN WESTERN KENYA

Indrani Saran[1], Laura Winn[2], Joseph K. Kirui[3], Diana Menya[4], Wendy P. O'Meara[1]

[1]Duke Global Health Institute, Durham, NC, United States, [2]Duke University, Durham, NC, United States, [3]Academic Model Providing Access to Healthcare (AMPATH), Eldoret, Kenya, [4]School of Public Health, College of Health Sciences, Moi University, Eldoret, Kenya

Integrated community case management programs are increasingly being scaled up across sub-Saharan Africa to expand care for common illnesses in areas where access to formal health facilities is limited. These programs rely on trained community health workers (CHWs) to help diagnose and treat illnesses such as malaria, pneumonia and diarrhea. Most CHWs do not receive a salary, but are instead offered a mix of financial and non-financial incentives for participation in these programs. There is little evidence, however, on CHWs' preferred combination of incentives, which is key to ensuring high levels of CHW performance as well as improved retention in their role. We conducted a discrete choice experiment with 199 CHWs in Western Kenya to investigate their preferences for different types of incentives. In the experiment, respondents made a series of choices between two hypothetical CHW positions with varying levels of mobile phone airtime, training, transport reimbursement, and levels of

community and health facility staff appreciation for their work; CHWs' choices reflect how much they value these different job characteristics relative to each other. We found that CHWs most preferred job characteristic was high levels of community appreciation for their work (mean β=1.74, P<0.01). For CHWs, a high level of community appreciation was approximately equivalent to receiving a 2000 Kenya Shillings (~US $20) monthly transport stipend (mean β=1.67, P<0.01) and about twice as valuable as appreciation from the health facility staff (mean β=0.90, P<0.01). Furthermore, although CHWs generally preferred more mobile phone airtime and more frequent trainings, these were less preferred incentives compared to either high levels of community appreciation or a transport reimbursement. Our results demonstrate that CHWs value both financial and non-financial incentives. Moreover our findings suggest that investing in efforts to improve community members' knowledge and recognition of CHWs' contribution to community health may have a significant impact on CHWs' motivation and retention in their role.

2111

IMPACT OF ONE-ON-ONE DETAILING AND MASS MEDIA ON COMMUNITY USE OF ORS AND ZINC DURING A SCALE-UP PROGRAM IN GUJARAT AND UTTAR PRADESH

Leslie Wentworth[1], Felix Lam[1], George Pro[2], Shreya Agrawal[3], Vishal Shastri[4], Melinda Stanley[1], Nitin Beri[5], Kate Schroder[1], Marta R. Prescott[1], Naresh Trikha[5]

[1]Clinton Health Access Initiative, Boston, MA, United States, [2]University of Iowa College of Public Health, Iowa City, IA, United States, [3]Teach for America, New York, NY, United States, [4]Alive & Thrive/FHI Solutions LLC, Delhi, India, [5]Clinton Health Access Initiative, Delhi, India

The Clinton Health Access Initiative implemented a comprehensive, large-scale program to increase use of ORS and zinc as a treatment for diarrhea in India. The program included detailing private rural health care providers (RHCPs, a major source of care in India) to promote, share information about, and offer direct sales of ORS and zinc. A mass media campaign was also run concurrently to improve caregiver knowledge and demand for ORS and zinc. Using a difference-in-difference quasi-experimental approach we evaluate the potential impact of the detailing activities in Uttar Pradesh and Gujarat, as well as any additional effect of the mass media campaign on the likelihood of a child with diarrhea being treated with ORS or combined ORS and zinc. Twenty two of 31 districts in Gujarat and 39 of 75 districts in UP were purposely assigned to receive the detailing intervention, and the media campaign reached all districts. Cross-sectional surveys were conducted in detailed and non-detailed districts at two time points. Multilevel multiple logistic regression models were constructed and adjusted for relevant covariates and change over time. A total of 1,828 under-5 diarrhea cases in Gujarat and 4,624 in UP were captured and analyzed. Irrespective of media exposure, the odds of being treated with ORS were significantly higher for children living in detailed districts than those in non-detailed districts (Gujarat aOR 4.05, 95% CI 2.9, 5.5; UP aOR 1.61 95% CI 1.0, 2.6); in Gujarat, the odds of receiving both ORS and zinc were significantly greater for children in detailed districts when compared to those in non-detailed districts (aOR 4.80, 95% CI 1.1, 20.1). For children whose caregiver was exposed to the media campaign, the odds of receiving ORS were higher for children in detailed districts as compared to those in non-detailed districts (Gujarat aOR 5.75, 95% CI 3.3, 9.9; UP aOR 1.77, 95% CI 1.6, 2.0). This highlights the benefit of program design that addresses barriers on both the demand and supply side simultaneously, as the media campaign was found to have an amplifying effect on the positive impact of detailing activities when implemented together.

2112

HOW GROUP-BASED CARDIOVASCULAR HEALTH EDUCATION AFFECTS TREATMENT ADHERENCE AND BLOOD PRESSURE CONTROL AMONG INSURED HYPERTENSIVE NIGERIANS: A PRE-TEST, POST-TEST STUDY

Aina Odusola[1], Heleen Nelissen[2], Marleen Hendriks[3], Constance Schultsz[2], Ferdinand Wit[2], Oladimeji Bolarinwa[4], Tanimola Akande[4], Charles Agyemang[5], Gbenga Ogedegbe[6], Kayode Agbede[7], Peju Adenusi[8], Akin Osibogun[9], Karien Stronks[5], Joke Haafkens[10]

[1]Department of Community Health and Primary Health Care, Lagos State University Teaching Hospital, Lagos, Nigeria, [2]Department of Global Health, Amsterdam Institute for Global Health and Development, Academic Medical Center, University of Amsterdam, Amsterdam, Netherlands, [3]Joep Lange Institute, Amsterdam, Netherlands, [4]Department of Epidemiology and Community Health, University of Ilorin Teaching Hospital, Ilorin, Nigeria, [5]Department of Public Health, Academic Medical Center, University of Amsterdam, Amsterdam, Netherlands, [6]Division of Health and Behavior, Center for Healthful Behavior Change, Department of Population Health, New York University School of Medicine, New York, NY, United States, [7]Ogo Oluwa Hospital, Bacita, Nigeria, [8]Hygeia Community Health Care, Hygeia HMO, Lagos, Nigeria, [9]Department of Community Health, Lagos University Teaching Hospital, Lagos, Nigeria, [10]Amsterdam Institute for Advanced Labour Studies, University of Amsterdam, Amsterdam, Netherlands

Cardiovascular diseases (CVD) are a major cause of death globally. Hypertension is a significant risk factor for CVD. To limit CVD access to affordable care is important. In sub Saharan Africa, access to affordable hypertension care is increasing through health insurance. Yet, hypertension treatment outcomes often remain poor due to poor adherence. Patient-centered educational tools can redress this. Using pre-test/post-test design, we investigated the effects of a structured cardiovascular health education program (CHEP) on treatment adherence, blood pressure (BP) control and body mass index (BMI) among Nigerian hypertensive patients who received guideline-based care in a rural primary care facility, in the context of community based health insurance. Participants were 149 insured patients with uncontrolled BP and/or poor self-reported medication adherence after 12 months of guideline-based care. All patients got 3 group-based educational sessions and usual primary care over 6 months. We evaluated changes in self-reported adherence to prescribed medications and behavioral advice (primary outcomes); systolic BP (SBP) and/or diastolic BP (DBP) and BMI (secondary outcomes); and beliefs about hypertension and medications (exploratory outcomes). Outcomes were analyzed with descriptive statistics and regression analysis. 140 patients completed the study (94%). At 6 months, more participants reported high adherence to medications and behavioral advice than at baseline: respectively, 101 (72%) versus 70 (50%), ($p < 0.001$) and 126 (90%) versus 106 (76%), ($p < 0.001$). Participants with controlled BP doubled from 34 (24%) to 65 (46%), ($p = 0.001$). The median SBP and DBP decreased from 129.0 to 122.0 mmHg, ($p = 0.002$) and from 80.0 to 73.5 mmHg, ($p < 0.001$), respectively. BMI did not change ($p = 0.444$). Improved medication adherence was associated with a decrease in medication concerns ($p = 0.045$) and improved medication self-efficacy ($p < 0.001$). By positively influencing patient perceptions of medications, CHEP strengthened medication adherence and, consequently, BP reduction among insured hypertensive Nigerians. This educational approach can support cardiovascular disease prevention programs for Africa's growing hypertensive population.

EVALUATION OF ANTIMICROBIAL PRESCRIBING PATTERNS AT A REFERRAL HOSPITAL IN RURAL TANZANIA

Matthew S. Haldeman[1], Antony Nsojo[2], Megan Seddon[3], Anthony Sangare[2], Peter Kishimbo[2], Davance Mwosomola[2], Jeff Hall[1], Mark Shaffer[1], Gabrielle Furgiuele[3], P. Brandon Bookstaver[3]

[1]University of South Carolina School of Medicine, Columbia, SC, United States, [2]Mbeya Zonal Referral Hospital, Mbeya, United Republic of Tanzania, [3]University of South Carolina College of Pharmacy, Columbia, SC, United States

Bacterial resistance to antibiotics is a growing concern worldwide, with Sub-Saharan Africa being no exception. It is unclear what role inpatient antibiotic use plays in this growing problem, as antibiotic stewardship efforts are largely absent in this region and prescribing patterns are not well documented. We evaluated the current antibiotic prescribing patterns and patient access to antibiotic therapy at Mbeya Zonal Referral Hospital in rural Tanzania. We chronologically reviewed 155 unique inpatient adult medical records from admissions in January-February 2018, of which 100 utilized inpatient antibiotic therapy. Metrics for evaluation included documentation of infectious diagnoses, diagnostics obtained, choice and duration of antibiotic therapy administered, antibiotic course completion, patient health insurance status, and antibiotic cost data based on patients' method of payment. Data were summarized using descriptive statistics. Within the 100 patient records involving antibiotic therapy, 171 antibiotic courses were noted, of which 153 were evaluable. Patients received the entire prescribed course of antibiotic therapy 43.8% (67/153) of the time. Ceftriaxone and metronidazole, the most commonly used antibiotics, were administered in 40.4% (69/171) and 24.0% (41/171) of courses, respectively. Among patients who received antibiotic therapy, 38% (38/100) had health insurance. The most common documented infectious diagnosis was unspecified pneumonia. Of patients who received antibiotics, 27% (27/100) had no infectious diagnosis documented and 18% (18/100) had a culture of any type obtained. In summary, inpatient antibiotic utilization patterns at a teaching hospital in rural Tanzania are frequently suboptimal. Therapy is often abbreviated, documentation is sometimes incomplete, and diagnostic confirmation is frequently not performed, all of which may contribute to increasing antibiotic resistance. Lack of insurance coverage and thus cost of therapy is likely a significant contributor to this problem. These data may be used to enhance stewardship efforts and guide hospital policy in the future.

ACCESS TO QUALITY CARE FOR PNEUMONIA, DIARRHEA, AND MALARIA AMONG CHILDREN UNDER FIVE IN RURAL MALI

Emily Treleaven[1], Jenny Liu[2], Eric Schatzkin[2], Caroline Whidden[3], Nancy Padian[4], Souleymane Cissouma[5], Beydi Cisse[3], Yacouba Samake[3], Youssouf Keita[3], Djoumé Diakite[3], Mohamed Traore[3], Naïmatou Kone[3], Kassoum Kayentao[6], Ari Johnson[3]

[1]University of Michigan, Ann Arbor, MI, United States, [2]University of California San Francisco, San Francisco, CA, United States, [3]Muso, Bamako, Mali, [4]University of California Berkeley, Berkeley, CA, United States, [5]Ministry of Health, Bamako, Mali, [6]Malaria Research and Training Center, Bamako, Mali

Rural Mali has one of the highest rates of child mortality globally; however, provider quality and access to care for common childhood illnesses in this setting have not been well studied. Using baseline data from a cluster-randomized trial, we conducted a comprehensive analysis of care seeking and treatment patterns for pneumonia, diarrhea, and malaria. From December 2016 to February 2017, mothers of 19,556 children under age five completed a household survey. Respondents provided information about whether children experienced diarrhea, fever, and/or cough in the preceding two weeks, care sought, and treatment received. We used mixed-effects regression models to assess odds of illness, likelihood of attending any care, care with a trained provider, and treatment according to protocol [oral rehydration therapy (ORT) and zinc for diarrhea without bloody stools, antimalarials for presumptive malaria (artemisinin combination therapy, quinine, artusenate, arthemeter), amoxicillin for uncomplicated pneumonia] adjusted for distance to nearest primary health center, child age/sex, household wealth, and maternal education. Among all children, 13.7% reported diarrhea without bloody stools, 3.4% reported fever and received a malaria rapid diagnostic test, and 4.9% reported cough with fast breathing. Of these 3,132 children, 60.3% accessed any provider; 13.7% attended a trained provider. Overall, 12.9% of children received correct treatment. Correct treatment rates were lowest for diarrhea without bloody stools (1.3%) and highest for presumptive malaria (49.0%). In adjusted models, attending a trained provider significantly predicted receipt of ORT and zinc (AOR=15.95, 95% CI 6.40 - 39.75) and amoxicillin (AOR=2.71, 95% CI 1.48 – 4.93), but not correct treatment for presumptive malaria. However, distance to nearest primary health facility was associated with receipt of antimalarials (AOR=1.58, 95% CI 1.19 – 2.09). Correct treatment of diarrhea, malaria, and pneumonia is low even among trained providers in rural Mali. Interventions should seek to improve quality among all providers while increasing access to trained providers.

NOTHING IN BIOLOGY MAKES SENSE EXCEPT IN THE LIGHT OF EVOLUTION: AN ALVEOLATE-CONSERVED MECHANISM IS IMPLICATED IN RHOPTRY SECRETION IN APICOMPLEXA

Eleonora Aquilini[1], Nicolas Dos-Santos Pacheco[1], Catherine Suarez[1], Marjorie Maynadier[1], Pilar Ruga Fahy[2], Jean-François Dubremetz[1], Maryse Lebrun[1]

[1]UMR 5235 CNRS, Université de Montpellier, Montpellier, France, [2]Pôle Facultaire de Microscopie Structurale, Geneva, Switzerland

Host-cell invasion by apicomplexan parasites is governed by coordinated and sequential exocytosis of specialized apical organelles: micronemes and rhoptries. Despite decades of research on parasite invasion our knowledge on membrane fusion events and exocytosis mechanisms of these organelles remains largely unknown. Together with ciliates and dinoflagellates, apicomplexan parasites belong to the *Alveolata* superphylum. Although morphologically different, *alveolates* share several features, including the presence of secretory organelles. Previous studies in *Paramecium tetraurelia* showed that their defensive extrusive organelles, termed trichocysts, have a characteristic arrangement of particles on the membrane over the docking sites: a ring of intramembranous particles with a "rosette" of 8-10 particles in the center. Rosette assembly is required for membranes fusion and, was shown to be essential for trichocyst secretion upon stimulation. Remarkably, a similar structure was observed at the apex of several apicomplexan parasites, which has remained uncharacterized to date. The dissection of mutants lacking the rosette and defective for trichocyst exocytosis (called ND for "non-discharge") prompted the identification of essential components of the trichocyst-membrane fusion machinery in *Paramecium*. We have identified, localized and characterized the orthologs of nd6 and nd9 in the apicomplexan model, *Toxoplasma gondii*. While TgND6 localizes to the apical pole of the parasites, TgND9 is located in the cytoplasm. Conditional depletion of TgND6 and TgND9 didn't affect parasites intracellular replication, egress or motility. Importantly, micronemes secretion also remains unaffected, but depletion of TgND6 or TgND9 abolishes rhoptry secretion and blocks the host-cell invasion process. This study identifies novel proteins essential for rhoptries secretion, supports our hypothesis of an Alveolate conserved mechanism for organelles-dependent membrane fusion events, and finally, offers a fresh perspective to explore such a fundamental and yet unclear basic process.

2116

THE GREAT ESCAPE: INVESTIGATING THE ROLE OF SERA6 IN MALARIA PARASITE EGRESS FROM THE RED BLOOD CELL

Michele Ser Ying Tan[1], James A. Thomas[2], Aaron Borg[1], Ambrosius P. Snijders[1], Michael J. Blackman[3]

[1]The Francis Crick Institute, London, United Kingdom, [2]London School of Hygiene & Tropical Medicine, London, United Kingdom, [3]The Francis Crick Institute and London School of Hygiene & Tropical Medicine, London, United Kingdom

Malaria is a devastating parasitic disease. Resistance of the most dangerous causative agent, *Plasmodium falciparum*, to frontline antimalarial drugs necessitates an improved understanding of parasite biology to facilitate new approaches to disease control or eradication. Malaria pathogenesis arises from replication of asexual blood stages in the human host. Merozoites invade erythrocytes, replicate within a parasitophorous vacuole (PV) then subsequently burst out of and destroy the erythrocyte in a process called egress. The released merozoites immediately invade fresh erythrocytes to repeat the cycle.

Malaria parasite egress is a key biological pathway with much potential for identification of novel drug targets. Work over several years has shown that egress is tightly controlled by a parasite enzyme cascade in which activation of the single cGMP-dependent protein kinase PKG triggers the discharge of a parasite serine protease called SUB1 into the lumen of the PV. SUB1 in turn proteolytically processes a PV-located cysteine protease called SERA6 in *P. falciparum*. Whilst SUB1 is required for all the morphological changes that lead up to egress, including PV membrane rupture, SERA6 is essential only for erythrocyte membrane rupture, the final step in egress. However, the exact molecular mechanisms underlying the role of SERA6 in egress remain a mystery. Here we present recent insights into the regulation of SERA6 activity and how the enzymatic function of SERA6 leads to cleavage of erythrocyte cytoskeletal components, resulting in its collapse and eventual lysis of the infected erythrocyte.

STUCK ON YOU: THE PLASMODIUM BASAL COMPLEX IS REQUIRED FOR PROPER DAUGHTER CELL SEGMENTATION

Rachel M. Rudlaff[1], Stephan Kraemer[2], Vincent A. Streva[3], Jeffrey D. Dvorin[4]

[1]Harvard Medical School, Boston, MA, United States, [2]Harvard University, Cambridge, MA, United States, [3]Boston Children's Hospital, Boston, MA, United States, [4]Harvard Medical School and Boston Children's Hospital, Boston, MA, United States

During the blood stage of malaria infection, *Plasmodium* parasites must asexually divide via schizogony during each 48-hour life cycle. Over the course of schizogony, a single parasite produces 20 to 30 daughter cells within a common cytoplasm that form into invasive merozoites by segmentation. The basal complex is hypothesized to be important for segmentation by 1) forming a contractile ring around nascent daughter cells, 2) connecting the inner membrane complex to the parasite plasma membrane, and 3) mediating membrane fusion to "clip" daughter cells from the residual body, completing cytokinesis. We identified a *Plasmodium* protein with no previously known function that is a novel basal complex protein, PF3D7_0407800, which we named coordinator of nascen[[Unsupported Character - Codename]]t cell detachment, or PfCINCH. Using CRISPR-Cas9 we generated a parasite line where PfCINCH can be inducibly knocked down with the TetR-DOZI system and determined that PfCINCH is required for asexual replication. By time-lapse microscopy, super-resolution fluorescence microscopy, and transmission electron microscopy we observed that parasites deficient in PfCINCH mature normally throughout the majority of the asexual life cycle and even egress at 48 hours post invasion; however, daughter cells contain multiple nuclei and sets of organelles in a single parasite plasma membrane. Additionally, by focused ion beam - scanning electron microscopy (FIB-SEM) we elucidated the 3D structure of these mutants. Taken together, this suggests that the *Plasmodium* basal complex is required for defining the boundaries of nascent daughter cells in schizogony. Finally, by immunoprecipitating PfCINCH complexes we have identified several novel members of the *Plasmodium* basal complex. Therefore, in this work we have applied several state-of-the-art techniques to describe the function of a previously uncharacterized protein and shed light on the protein components of *Plasmodium* segmentation machinery.

2118

PATCH-CLAMP OF THE *P. FALCIPARUM* DIGESTIVE VACUOLE IDENTIFIES A NOVEL CHANNEL AND ANTIMALARIAL TARGET

Gagandeep S. Saggu, Sanjay A. Desai

National Institutes of Health, National Institute of Allergy and Infectious Diseases, Rockville, MD, United States

The malaria parasite digestive vacuole (DV) is required for hemoglobin digestion and is the target of several antimalarial drugs including chloroquine. The DV is presumed to have multiple transmembrane channels and pumps to maintain an acidic internal pH, export amino acids, and mediate flux of antimalarial drugs. Study of these transporters has been limited to indirect transport measurements and has been complicated by imperfect DV enrichment from parasite lysates. We have now addressed these limitations with cell-attached patch-clamp of individual, intact DV membranes from *Plasmodium falciparum*. High resistance seals (> 10 Gohms) were obtained after optimizing pipette glass composition and geometry. A large-conductance channel (450 pS in 320 mosm salt solutions) was the primary channel seen, but additional smaller conductance channels have also been detected. The primary channel exhibited weak voltage-dependence at large imposed membrane potentials as well as unusual gating that suggests a two-pore configuration on the DV membrane. Progress on identification of this channel's molecular basis and the effects of antimalarial drugs and nutrients on channel activity will also be described. These findings indicate that the DV membrane has robust transport activity with features distinct from those of the mammalian lysosome. Identification and molecular characterization of transporters on the DV membrane will provide foundational insights into vacuolar biology, clarify the resistance mechanisms for several antimalarial drugs, and guide development of new therapies for malaria.

ANTIBODY RESPONSES AGAINST THE CANDIDATE VACCINE ANTIGENS *OV*-103 AND *OV*-RAL-2 ARE ASSOCIATED WITH PROTECTIVE IMMUNITY IN BOTH MICE AND HUMANS TO *ONCHOCERCA VOLVULUS* INFECTIVE LARVAE

Jovvian Parakkal[1], Sonia Jain[1], Jessica Hess[2], Nancy Tricoche[1], David Abraham[2], Sara Lustigman[1]

[1]The Lindsley F. Kimball Research Institute, New York Blood Center, New York, NY, United States, [2]Department of Microbiology and Immunology, Thomas Jefferson University, Philadelphia, PA, United States

Onchocerca volvulus, a filarial nematode is an etiologic agent of river blindness that infects approximately 17 million people, mostly in Africa. The current strategy for elimination of *O. volvulus* focuses on controlling transmission through ivermectin-based mass drug administration (MDA) programs. Due to several limiting factors such as potential ivermectin resistance, the lack of macrofilaricidal activity by ivermectin and the prolonged time line (>20 years) needed for transmission interruption, there is a growing concern that elimination of onchocerciasis cannot be achieved solely through the current strategy. Additional tools are critically needed including the use of a prophylactic vaccine. Presently *Ov*-103 and *Ov*-RAL-2 are the most promising vaccine candidates against *O. volvulus* infection. Protection induced by immunization of mice with the alum adjuvanted *Ov*-103 *or Ov*-RAL-2 vaccines appeared to be

antibody dependent as AID$^{-/-}$ mice that could not mount antigen-specific IgG1 antibody response were not protected. Moreover, when cells were blocked from entering the parasite microenvironment in vaccinated mice, killing of larvae did not occur; indicating that vaccine induced protective immunity was dependent on IgG and cell contact. To assess the association between antigen-specific antibody responses and anti-larvae immunity in humans, we analyzed the presence of anti-*Ov*-103 and *Ov*-RAL-2 cytophilic antibody responses (IgG1 and IgG3) in individuals classified as putatively immune and in infected individuals who developed concomitant immunity with age. In both groups approximately 90% of the individuals had elevated IgG1 and IgG3 responses to *Ov*-103 and *Ov*-RAL-2. Moreover, human monospecific anti-*Ov*-103 antibodies but not anti-*Ov*-RAL-2 inhibited significantly the molting of L3 larvae *in vitro* by 46% in the presence of naïve human neutrophils, while both anti-*Ov*-103 and anti-*Ov*-RAL-2 antibodies significantly inhibited the molting by 70-80% when cultured in the presence of naive human monocytes. We have also found that sera from both putatively immune and infected individuals had significantly high levels of chemokines such as KC, IP-10, MCP-1 and MIP-1β that are known to be associated with neutrophil and monocyte recruitment. The vaccines characterized in this study have the potential of reducing infection and thus morbidity associated with onchocerciasis in humans. If further developed for human use the stimulation of cytophilic antibodies that function in antibody-dependent cellular cytotoxicity would be of importance in such a vaccine.

2120

THE NOTCH SIGNALING PATHWAY CONTROLS BASOPHIL RESPONSES DURING HELMINTH-INDUCED TYPE 2 INFLAMMATION

Lauren Webb[1], S. P. Frueh[1], O. O. Oyesola[1], S. A. Peng[1], E. Kamynina[1], R. L. Cubitt[1], J. K. Grenier[2], C. G. Danko[3], E. D. Tait Wojno[1]

[1]Baker Institute for Animal Health and Department of Microbiology and Immunology, Cornell University College of Veterinary Medicine, Ithaca, NY, United States, [2]RNA Sequencing Core, Center for Reproductive Genomics and Department of Biomedical Sciences, Cornell University College of Veterinary Medicine, Ithaca, NY, United States, [3]Baker Institute for Animal Health and Department of Biomedical Sciences, Cornell University College of Veterinary Medicine, Ithaca, NY, United States

Type 2 inflammation is characterized by production of the cytokines IL-4, IL-5 and IL-13 and promotes clearance of gastrointestinal helminths, which infect over 2 billion people worldwide. Basophils are innate immune cells that accumulate in the intestine during infection with the helminth *Trichuris muris*, and are known to be potent producers of inflammatory mediators. However, the molecular mechanisms that control basophil function and gene expression during helminth-induced type 2 inflammation remain unclear. We show that during *T. muris* infection, basophils upregulated components of the Notch signaling pathway, which regulates gene expression programs during development and inflammation. *In vitro*, Notch inhibition abrogated basophil cytokine production by directly targeting *Il4* and *Il6* transcripts. Transcriptional profiling of Notch-deficient basophils revealed that Notch directs basophil responsiveness to inflammatory cues and effector gene expression. *In vivo*, Notch-deficient basophils did not localize effectively within the intestinal lamina propria during infection, and displayed decreased interaction with CD4$^+$ cells. Consequently, mice lacking basophil-intrinsic Notch signaling had impaired worm clearance and decreased intestinal type 2 inflammation following *T. muris* infection. These findings demonstrate that Notch regulates basophil gene expression and effector function during helminth-induced type 2 inflammation, with repercussions for our understanding of type 2 immunity, for development of effective therapeutics aimed at this arm of host defense.

Although chronic helminth infection has been associated with diminished allergic reactivity (hygiene hypothesis), the impact of pre-existing allergic sensitization on altering the outcome of helminth infection is less well-studied. Having previously demonstrated an augmented Th2-dominated parasite specific CD4+ response in the context of human helminth infection with coincident house dust mite (HDM) allergy, we sought to identify the mechanism driving this response and to understand how allergic sensitization may influence parasite burden at the site of inflammation. Using a murine model of HDM-induced allergic asthma and concomitant *Ascaris* spp. infection, our data show that HDM sensitization prior to infection with *Ascaris* induces a robust Th2 inflammation in the lung characterized by an increase in both IL-5/IL-13 producing type 2 innate lymphoid cells ($17.9x10^3$ cells vs $2.4x10^3$ cells, $p<0.01$) and eosinophils ($2.92x10^5$ cells vs $0.02x10^5$ cells, $p<0.001$) when compared to non-allergic infected animals. This allergen-driven inflammation in the lungs leads to an IL-4-rich environment (8.39 pg/mL vs 3.33 pg/mL, p=0.006) that drives the differentiation of lung macrophages towards the M2 phenotype expressing Arginase-1 (17.6-fold change, p=0.0142), but not iNOS. When the *Ascaris* larvae migrate from the circulation to the lung tissue in their quest to reach the airways in these HDM-sensitized mice, the Th2 inflammation leads to a 72% marked reduction in the number (20±9 larvae vs. 63±50 larvae; p=0.0443) and in the development of lung-stage *Ascaris* larvae (size 24816 μM^2 vs 58170 μM^2, $p<0.001$) when compared with non-allergic infected mice. When eosinophil deficient (ΔdblGATA) mice are infected with *Ascaris* following HDM-induced asthma, the numbers of larvae are no longer reduced (p=0.1800), nor is there any alternation in larval development when compared to ΔdblGATA non-allergic infected mice (p=0.08). Taken together, our data suggest that allergic sensitization coincident with helminth infection drives an eosinophil-rich pulmonary Th2 response that limit helminth parasite numbers and also directly hinder their development.

B CELLS ARE IMPORTANT DURING EARLY INFECTION IN SUPPORTING TH2 TYPE IMMUNE RESPONSES TO *TRICHURIS MURIS* INFECTION

Rinal Sahputra, Dominik Ruckerl, Kevin Couper, Andrew MacDonald, Werner Muller, Kathryn Else

Lydia Becker Institute for Immunology, University of Manchester, Manchester, United Kingdom

How B cells contribute to protective immunity against parasitic nematodes remains unclear, with their importance as regulatory cells under-explored. This study therefore investigates the role of B cells and antibodies in immunity to *Trichuris muris* (*T. muris*) infection using anti-CD20 mAb (Genentech) to deplete B cells prior to and post *T. muris* infection in both C57BL/6 and BALB/c strains of mouse. C57BL/6 mice receiving anti-CD20 treatment prior to infection failed to expel *T. muris* by d35 post infection (p.i.) and Th2 type cytokines produced by mesenteric lymph nodes cells were significantly lower than produced by cells from isotype control treated mice; in contrast, BALB/c mice were still able to expel the worms in the absence of B cells. To explore whether the susceptibility of C57BL/6 mice after anti-CD20 mAb treatment is due to the lack of B cells as antibody producers or as regulatory cells, we blocked IFN-γ using anti-IFN-γ mAb post B cell depletion. Interestingly, our data show that

worm expulsion now occurred by day 21 p.i. and the mice produced more *T. muris* specific IL-13, in the absence of *T. muris* specific antibodies. To investigate whether B cells are important in initiating or in maintaining Th2 type immune responses, we depleted B cells from day 14 p.i., culling mice at day 35 p.i. Surprisingly, removing B cells after the first two weeks post infection failed to prevent worm expulsion, with the balance of Th1/Th2 cytokines remaining the same to as seen in isotype control treated mice. Collectively, this study suggests that (a) the importance of B cells in mediating worm expulsion during *T. muris* primary infection varies according to genetic background and (b) the important role played by the B cell in resistance to infection is as a regulatory cell, acting to support Th2 type immune responses during the first two weeks post infection.

MALARIA PARASITE TRANSLOCON STRUCTURE AND MECHANISM OF EFFECTOR EXPORT

Chi-Min Ho[1], Josh R. Beck[2], Mason Lai[3], Yanxiang Cui[4], Daniel E. Goldberg[2], Pascal F. Egea[1], Z. Hong Zhou[1]

The putative Plasmodium Translocon of Exported Proteins (PTEX) is essential for transport of malarial effector proteins across a parasite-encasing vacuolar membrane into host erythrocytes, but the mechanism of this process remains unknown. Here we show PTEX is a bona fide translocon by determining near-atomic resolution cryoEM structures of the endogenous PTEX core complex of EXP2, PTEX150 and HSP101, isolated from Plasmodium falciparum in the engaged and resetting states of endogenous cargo translocation with CRISPR/Cas9-engineered epitope tags. Our work reveals the mechanism of P. falciparum effector export, enabling structure-based design of drugs targeting this unique translocon.

PLASMODIUM AND HOST MICROBIOTA: FRIEND OR FOE?

Debanjan Mukherjee[1], Angelo Ferreira Chora[1], Ricardo Ramiro[2], Isabel Gordo[2], Maria M. Mota[2]

In malaria endemic areas, *Plasmodium*, the causative agent of malaria, and bacterial co-infections are highly concurrent, often with fatal outcomes like cerebral malaria(CM), acute lung injury (ALI) and severe anemia. Recently, it has been shown in patients from Sub-Saharan Africa that *Plasmodium* infection predisposes to high bacteremia. However, the causal link between *Plasmodium* infection and increased bacteremia and the putative mechanisms involved behind severe malaria associated pathology is currently unknown. In the present study, using different models of rodent malaria we show that infection with *Plasmodium* parasites causes an increase in the bacterial diversity in the lung specifically of mice that die of ALI. Moreover, we show by genetic knockout and complementation studies that this increase in the tissue specific bacterial load was dependent on parasite sequestration in the lung. Metagenomics analysis of the bacterial community showed marked alterations in the lung microbiome of mice that die of ALI. We report here that this increase in the bacterial burden is not associated with increased intestinal permeability or with histological alterations in the intestinal barrier. These alterations in the lung microbiome was significantly correlated with high levels of alveolar inflammation (IL-6, IL-10, IFN-γ and TNF-α). To definitively assess the impact of microbiota changes during *Plasmodium* infections on the clinical outcome of infection, germ free mice infected with *Plasmodium* strains causing lung injury had a significant delay in death (with majority dying with hyperparasitemia) compared to specific pathogen free mice. Interestingly, targeting specific microbiota of the lung with antibiotics prevented malaria associated ALI in mice and prolonged survival. All these results suggest that *Plasmodium* blood stage-mediated immunomodulation may result in aberrant expansion of bacteria in the lungs during malaria infection and also pave the way for interventional studies for malaria associated ALI.
